Beliefs as a Means of Self-Control? Evidence from a Dynamic Student Survey

Abstract

We repeatedly elicit beliefs about the returns to study effort, in a large university course. A behavioral model of quasi-hyperbolic discounting and malleable beliefs predicts that the dynamics of beliefs mirrors the importance of exerting self-control, such that believed returns increase as the exam approaches, and drop post-exam. Exploiting variation in exam timing to control for common information shocks, we find this prediction confirmed: average believed study returns increase by about 20% over the period before the exam, and drop by about the same afterwards. Additional analyses further support the hypothesized mechanism that beliefs serve as a means of self-control.

JEL-Codes: C810, D810, D910.

Keywords: beliefs, present bias, self-control, effort, survey.

We thank Yves Breitmoser, Anna Gumpert, Andreas Haufler, Peter Schwardmann, Felix Weinhardt and Florian Zimmermann for insightful discussions, and our various seminar and conference audiences for helpful comments. Special thanks go to Martina Albers who was involved in early stages of this project. Financial support by the Deutsche Forschungsgemeinschaft through CRC TRR 190 (project number 280092119) and by the European Research Council (ERC Starting Grant 263412) is gratefully acknowledged.

Declarations of interest: none.

1 Introduction

People exhibit systematically biased beliefs in a variety of domains.¹ To a classical decision maker, these biases are often costly, and neutral at best. Economists therefore assess evidence of belief biases mostly from a “mistakes” perspective. But biased beliefs can also serve to overcome a self-control problem (see, e.g., [Bénabou and Tirole, 2002](#)), and they may thereby improve material outcomes for a behaviorally biased decision maker. In this paper, we provide the first direct field evidence that beliefs about the *returns* to costly effort with delayed benefits indeed systematically respond to this instrumental motive, i.e., that beliefs serve as a means of self-control.

We investigate the dynamics of students’ beliefs about the effectiveness of study effort for exam performance. Studying for an exam has immediate costs and delayed rewards, which are the typical features of a self-control problem that arises due to present bias (see, e.g., [Ariely and Wertenbroch, 2002](#); [Augenblick, Niederle, and Sprenger, 2015](#); [Clark, Gill, Prowse, and Rush, 2020](#); [Cheung, Tymula, and Wang, 2022](#), for related evidence). To examine whether beliefs may be used to overcome this self-control problem, we exploit a time pattern: the returns to studying for an exam increase as the exam comes closer in time, implying that the importance of the self-control problem grows, too. Under instrumental belief distortion, the students’ return beliefs should therefore be upward-biased most when the exam is imminent.

To guide our empirical design and analysis, we first formalize this intuition with a simple behavioral model of (β, δ) -discounting and malleable beliefs. The model indeed yields the prediction that the decision maker’s subjectively expected return to effort is most upward-biased in the final study period before the exam, when self-control is most valuable, and also that it sharply drops in hindsight, when the exam is over and the instrumental motive gone.

We then design a dynamic student survey to test the model’s predictions on a sample of students in a large university course (first-year Bachelor’s microeconomics). Our main variable of interest is a student’s belief about an unknown entity: the difference between

¹There is a large literature in both psychology and economics demonstrating overconfidence and other belief biases, see the survey by [DellaVigna \(2009\)](#). For a quick introduction to the psychology literature on unrealistic optimism, following the seminal work by [Weinstein \(1980\)](#), see [Shepperd, Waters, Weinstein, and Klein \(2015\)](#).

(i) her performance (measured in point-score percentage) if she were to study for 40 hours during the last two weeks before the exam, and (ii) her performance if she were to study for 20 hours during the same period. Both subjective expectations are elicited at multiple points in time, keeping the target—the return to studying in the last two weeks prior to the exam—constant.

Notice that if information shocks about this target were i.i.d. across students, then their average belief, if formed rationally, should not change over time (the martingale property). In this case, any theory predicting non-trivial belief dynamics could easily be tested against the null hypothesis of rational expectations. However, the students' information shocks are correlated due to their common experiences in lectures, class tutorials, and other common observations that inform them about the returns to studying. We therefore rely on a particular feature of the university's exam organization (see Section 4.1 for details): we compare beliefs between two groups of students that take the course's final exam at different points in time. The two groups are indistinguishable from the instructors' perspective, they share the same lectures and class tutorials, and have access to the same information throughout the course. But the two groups vary in the importance of self-control because one group's exam comes several weeks earlier. Indeed, various demographic variables or even beliefs elicited in the initial survey do not allow to predict group membership, supporting the use of one group as control group for the other.

We find that, for each of the two groups, average beliefs follow the model's predicted pattern over time, *relative to their respective exam*: return beliefs increase towards the final study period before one's own exam and sharply drop post-exam. No such reaction occurs around the time that the other group has their exam. Quantitatively, believed returns show an average increase of around 20% in the period before the exam, which largely disappears post-exam and is unaffected by various control variables. When we combine both groups into a single pool, we find that initial and final average return beliefs coincide, suggesting unbiased baseline priors in combination with a build-up of beliefs in the effectiveness of studying during the exam preparation.

Although 214 students responded in the survey's first wave, our main analysis is based on a subsample of only 84 students that completed all waves and could be unambiguously as-

signed to one exam date based on additional administrative data. All regression coefficients concerning our hypotheses show the predicted sign, but we obtain statistical significance only when we pool the two exam dates. It is worthwhile noting, however, that selective attrition would most likely leave us with students that suffer less-than-average from present bias (for related evidence, see, e.g., [Harrison, Lau, and Yoo, 2023](#)), whereby effects may be underestimated. Moreover, additional analyses further support the hypothesized mechanism. First, we find evidence for the assumption that students experience a self-control problem, in the sense that they systematically over-predict their future study effort.² In light of the model, this provides a possible motive for biased beliefs about study returns. Second, we confirm our main results when restricting the non-exam-writing control students to those that after the respective exam also report knowing the exam questions (which became publicly available right after each exam). The effects are therefore not driven by surprising exam content. Third, additional data relating to another course taken by a subset of our sample (introductory mathematics) delivers qualitatively similar results. Importantly, these data also show that the students’ tendencies to report beliefs that change in the predicted manner are correlated between the two courses. This is exactly what one would expect if—despite potential differences in intrinsic motivation between courses—present bias, as a stable individual characteristic, was an important driver of beliefs. Finally, other correlations are also in line with the model: students with a greater upward bias before the exam show a larger drop in their return beliefs right after the exam, and these belief movements are positively correlated with the extent of over-predicting one’s own effort.

2 Related Literature

Our point of departure is the general idea that belief distortions may be instrumental in overcoming a self-control problem. In influential work, [Bénabou and Tirole \(2002\)](#) make this point by combining (β, δ) -discounting (e.g., [Laibson, 1997](#), or [O’Donoghue and Rabin, 1999](#)) with imperfect self-knowledge, where belief distortions concern *intrinsic* personal character-

²While this evidence for present bias is only indirect, that studying is negatively affected by present bias for a significant proportion of students appears to be an assumption that is as standard as it is empirically well-founded in the literature.

istics (ability or preferences) and arise from sophisticated self-persuasion of the kind that bad news may be optimally forgotten.³ By contrast, we study belief distortions about the largely extrinsic return to effort and propose a reduced-form model of belief manipulation. Importantly, our model also differs in terms of its predictions in two important ways: first, it yields optimal belief distortions also under naïveté about the self-control problem, and second, it generates systematic belief distortions that violate Bayesian updating.⁴

We extend the multiple-selves model with (β, δ) -discounting by an over-arching unbiased “planner” who can directly (and sub-consciously, for the decision-making “doer”) distort the return beliefs and thereby achieve self-control. While the model is thus related to various dual-systems theories (e.g., [Thaler and Shefrin, 1981](#); [Fudenberg and Levine, 2006](#); [Brocas and Carrillo, 2008](#)), none of these feature malleable beliefs. Moreover, while our model shares the feature of optimal (sub-conscious) belief choice with [Akerlof and Dickens \(1982\)](#), [Brunnermeier and Parker \(2005\)](#), [Gollier and Muermann \(2010\)](#) and [Bracha and Brown \(2012\)](#), the motive for belief distortion is different: it is instrumental self-control rather than non-instrumental anticipatory pleasure. Indeed, for the case of dynamic consistency ($\beta = 1$), belief distortion is never optimal in our model. It is worthwhile noting that “feel-good” belief bias—regardless of whether it stems from an anticipatory utility motive ([Loewenstein, 1987](#)) or an ego utility motive ([Kőszegi, 2006](#))—would concern the exam score for any given study effort, whereas to be instrumentally effective, belief bias has to concern the *returns* to effort, i.e., the effect on the exam score of changing study effort. Put simply, none of these non-instrumental motives make a clear prediction for our elicitation of the returns to effort, which involve counterfactuals, whereas the instrumental/self-control motive does. Our abstraction from non-instrumental motives is thus not to deny their relevance, but rather to focus on the mechanism of interest due to present bias, which also policy research highlights as well as confirms as a key challenge to students (e.g., [Levitt, List, Neckermann, and Sadoff, 2016](#);

³Relatedly, [Brocas and Carrillo \(2000\)](#), and [Carrillo and Mariotti \(2000\)](#) show that information avoidance can be optimal under dynamic inconsistency. [Compte and Postlewaite \(2004\)](#) study a model where confidence enhances the probability of success on a task that is performed repeatedly and show that a positively biased perception of one’s chance of success is then optimal and can be maintained even in the long run.

⁴[Bénabou and Tirole \(2002\)](#) maintain full sophistication about how memory is manipulated, so Bayesian updating delivers that the average posterior belief equals the prior. From the more recent perspective of [Kamenica and Gentzkow \(2011\)](#), their model is therefore one of Bayesian (self-) persuasion (relatedly, see also [Mariotti, Schweizer, Szech, and von Wangenheim, 2023](#)).

Himmler, Jäckle, and Weinschenk, 2019).⁵

Evidence that self-control problems cause belief bias is hard to come by, and accordingly scarce. This is especially true for evidence from the field, with “naturally occurring” tasks. Our approach exploits the natural dynamic variation in the importance of self-control. At a basic level, the repeated elicitation of beliefs around an exam puts us close to research in psychology on the temporal evolution of confidence—as one particular category of “unrealistic optimism” (see Windschitl and Stuart, 2015)—which is measured by beliefs about how well one will or did perform a self-relevant task (typically, students’ predictions of their grade on an exam). A main and robust insight from this research is that such confidence decreases in the temporal proximity to the time of performance (see seminal work by Nisan, 1972; Gilovich, Kerr, and Medvec, 1993).⁶ In recent work, Ma (2020) follows up on this paradigm and elicits economics students’ grade predictions on an essay three times over several weeks – first, well before essay submission, second, shortly after submission, and finally, shortly before grade release. He finds that (average) confidence drops following submission and then stays constant. His work is closest to ours, since it also studies the dynamics of beliefs, in a similar natural university setting, and with the same conceptual innovation relative to psychology as ours, namely that belief bias may not only be motivated by emotional benefits but also by instrumental benefits under a self-control problem. Indeed, he also uses a model to make this point, and based on this interprets his findings as supporting the instrumental motive (self-control) but rejecting the consumption motive (anticipatory utility). While Ma’s findings (and also those from earlier psychology studies) are in line with ours, there are several important differences in approach. First, we focus directly on the innovative element of the instrumental motive of self-control, both theoretically and empirically; in particular,

⁵Indeed, see Breig, Gibson, and Shrader (2020) and Cordes, Friedrichsen, and Schudy (2023), for experimental evidence supporting the relevance of (also) anticipatory utility for procrastination in completing an exogenously given number of tasks over multiple time periods (see Brunnermeier, Papakonstantinou, and Parker, 2017, for a purely belief-based theory of procrastination). Relatedly, Engelmann, Lebreton, Salem-Garcia, Schwardmann, and van der Weele (2023) provide direct causal evidence of wishful thinking to alleviate anxiety about adverse future outcomes.

⁶Grimes (2002) shows this for economics students. There is also evidence of defensive pessimism developing shortly before the self-relevant feedback among individuals with low self-esteem (Shepperd, Ouellette, and Fernandez, 1996). Relatedly, Chen and Schildberg-Hörisch (2019) experimentally provide the first causal evidence that (absolute) confidence has a motivational value, and Banerjee, Gupta, and Villeval (2020) further show confidence spillovers between unrelated tasks in a field experiment in India.

we therefore elicit beliefs about what is instrumentally relevant, namely the returns to effort. Second, we are able to exploit the fact that there are two exclusive exam dates in order to use non-exam-writers as a control group for exam writers in this natural/field setting. This allows linking the difference in beliefs to the difference in instrumental motives between the two groups, controlling for correlated information and other common shocks.⁷ Third, and consequently, our model is substantially different from [Ma's](#): (i) our model cleanly focuses on the instrumental motive in that it predicts unbiased beliefs absent present bias;⁸ (ii) because we have a control group, it includes two pre-performance periods (vs. a single one); (iii) our planner-doer modeling approach means instrumental belief distortion is a viable self-control mechanism also under naïveté (vs. sophistication). Incidentally, these differences from [Ma \(2020\)](#) as well as the aforementioned psychology literature also summarize our main methodological and conceptual contributions.

Two experiments complement our study and support our conclusions in parts where our field evidence is naturally less cleanly controlled. At the same time, relative to our study, they come with the caveats of using artificial tasks and the short time horizon of a typical laboratory session, where the assumption of a self-control problem due to present-biased utility discounting is somewhat questionable (for an alternative psychological account, see [Muraven and Baumeister, 2000](#); [Baumeister, Vohs, and Tice, 2007](#)). First, [Huck, Szech, and Wenner \(2018\)](#) study costly effort provision under different information about the piece rate. They find that not (yet) knowing whether the piece rate is high or low strongly increases participants' effort in terms of how many tedious tasks they complete to essentially the level of those knowing they face the high wage; and indeed, a third of participants also choose to avoid freely available wage information. Not only can these findings be explained by a one-period effort provision version of our model (assuming low mental costs of belief distortion), they also indicate potentially large instrumental benefits of being able to distort one's return beliefs (for which we only have suggestive evidence, see our [Section 5.3](#)).⁹

⁷Also [Ma](#) points out that such common learning is a concern with the psychology studies of exam grade predictions, though he argues that using an essay rather than an exam alleviates this concern.

⁸[Ma's](#) modeling of the instrumental motive includes an anticipatory utility component. Even without any regulating effect on effort, his model implies inflated confidence when the cost of belief distortion is low: taking the objective in his equation (14), any belief θ^I greater than the true θ yields greater utility when ψ is sufficiently small.

⁹The authors themselves pitch “plain” present bias against motivated beliefs, but not their combination.

Second, while in [Huck et al.](#)'s experiment, participants either have perfect wage information or face a given wage lottery (beliefs are not elicited), [Lobeck \(2022\)](#) elicits *belief updating* from a noisy signal about whether they will be paid according to effort on a tedious task or according to a random draw (i.e., luck). While all participants ultimately have to perform the task a second time, in the same “payoff state,” [Lobeck](#)'s treatment varies whether beliefs are elicited before or after they learn about this second task. He finds that participants' updated beliefs that effort pays are greater for those who already know they will have to perform again, and this appears driven by differences in processing discouraging information.¹⁰ Though in a binary setting (effort either pays or does not at all) and without our temporal dimension, [Lobeck](#)'s findings therefore further support that return beliefs respond to the instrumental motive of self-control, and they also offer the additional insight that this may be driven in particular by positively biased processing of discouraging information.¹¹

From a purely empirical perspective our work is also related to tests of rational expectations in the field, where the researcher does not observe (or control) all information that agents receive (e.g., [Bernheim, 1990](#); [Benítez-Silva and Dwyer, 2005](#)). Whereas this literature essentially relies on the assumption of i.i.d. forecast errors in their tests of the rational expectations hypothesis, our empirical strategy is able to control also for correlated information.

3 Theoretical Background

We first model the “study problem” of a present-biased student, whom we call Sue, taking an exam at a fixed date. To formalize the intuition that Sue's beliefs about the returns to effort respond to the instrumental benefits of overcoming her self-control problem, we then introduce a self-regulatory system—Sue's “planner”—that subconsciously chooses her beliefs at some mental cost.

¹⁰This supports the good-news-bad-news asymmetry in updating put forward by [Sharot, Korn, and Dolan \(2011\)](#), for which evidence is otherwise rather mixed, however (e.g., see the handbook chapter discussion by [Benjamin, 2019](#)).

¹¹If one were to consider deception a self-control problem, then also the experiment by [Schwardmann and van der Weele \(2019\)](#) is similarly related. They find that people deceive themselves (more) into confidence about an IQ test performance when facing incentives to subsequently deceive others. Meanwhile, see also [Schwardmann, Tripodi, and van der Weele \(2022\)](#) for field evidence.

Sue’s study problem consists of three periods. In the first two periods, $t = 1, 2$, Sue exerts study effort e_t at cost $c(e_t) = \frac{e_t^2}{2}$ in preparation for her exam, which takes place at the end of period 2. She receives her grade

$$g(e_1, e_2, R) = R \cdot (e_1 + e_2) \tag{1}$$

in period 3, where R is the return to her effort, and she trades off her desire to achieve a higher grade against the cost of higher study effort.

Importantly, Sue faces uncertainty about R , where we denote by \hat{R}_t her expectation as of the beginning of period t , and she faces a self-control problem in the form of quasi-hyperbolic discounting (present bias), with parameters $(\beta, \delta) \in (0, 1)^2$. Given belief \hat{R}_t in period t , and assuming risk neutrality, she chooses effort e_t to maximize utility U_t , given by

$$\begin{aligned} U_1(e_1, e_2 | \hat{R}_1) &= -\frac{e_1^2}{2} - \beta\delta\frac{e_2^2}{2} + \beta\delta^2\hat{R}_1 \cdot (e_1 + e_2) \text{ and} \\ U_2(e_1, e_2 | \hat{R}_2) &= -\frac{e_2^2}{2} + \beta\delta\hat{R}_2 \cdot (e_1 + e_2), \end{aligned}$$

respectively, for the two periods $t = 1, 2$.

Her optimal effort in t , as a function of her return belief, is therefore

$$e_t(\hat{R}_t) = \kappa_t \hat{R}_t \text{ for } \kappa_1 = \beta\delta^2, \kappa_2 = \beta\delta.$$

Sue under-provides effort due to her present bias, $\beta < 1$: for given return beliefs \hat{R}_t , an unbiased Sue would want greater effort in both periods. Moreover, Sue exerts greater effort the closer she finds herself to the exam, since the reward of a better grade weighs more heavily in the later period ($\kappa_2 > \kappa_1$).¹²

This completes the description of Sue as a “doer,” for given return beliefs. We now turn to the main focus of our model, the determination of beliefs. They are chosen by Sue’s planner, who has the same preferences except that she has no present bias ($\beta = 1$). We think of the planner as a subconscious self-regulatory system with the sole capacity to

¹²Even with perfect long-run patience ($\delta = 1$), this would obtain upon assuming that $g = R \cdot (\phi e_1 + e_2)$, with $0 < \phi < 1$, so that early study effort “depreciates.” For simplicity, we ignore this realistic aspect here.

distort the doer’s perception of environmental uncertainty in order to overcome her self-control problem. Since the planner has to somehow suppress what the doer “knows,” we also assume that belief distortion has some mental cost, increasing in the intensity of self-delusion (this follows [Bracha and Brown, 2012](#); see [Coutts, 2019](#), for supporting evidence).¹³

Concretely, for each t , the planner chooses belief \hat{R}_t at cost $b_t = \gamma \frac{1}{2} (\hat{R}_t - \hat{R}_0)^2$, where $\gamma > 0$ is a scaling-parameter and $\hat{R}_0 > 0$ is Sue’s planner’s belief in period $t = 0$. Under the simplifying assumption that no information arrives during $t = 0, 1, 2$, Sue’s planner maximizes¹⁴

$$V(\hat{R}_1, \hat{R}_2, \hat{R}_3 | \hat{R}_0) = -\frac{e_1(\hat{R}_1)^2}{2} - \delta \frac{e_2(\hat{R}_2)^2}{2} + \delta^2 \hat{R}_0 \cdot (e_1(\hat{R}_1) + e_2(\hat{R}_2)) - \gamma \frac{1}{2} (\hat{R}_1 - \hat{R}_0)^2 - \delta \gamma \frac{1}{2} (\hat{R}_2 - \hat{R}_0)^2 - \delta^2 \gamma \frac{1}{2} (\hat{R}_3 - \hat{R}_0)^2. \quad (2)$$

Correctly predicting the doer’s effort response, the planner trades off instrumental benefits and mental costs of belief distortion. The solution to this problem is (where we let $\kappa_3 \equiv 0$):

$$\hat{R}_t^* = \hat{R}_0 \cdot \left(1 + \frac{1 - \beta}{\beta} \cdot \frac{\kappa_t^2}{\kappa_t^2 + \gamma} \right). \quad (3)$$

Before her exam, Sue will come to believe that the returns are excessively high, and the more so the closer is the exam ($\hat{R}_2^* > \hat{R}_1^* > \hat{R}_0$). After the exam, there is no instrumental value to costly self-delusion, hence her return beliefs will be undistorted ($\hat{R}_3^* = \hat{R}_0$).

Indeed, the only reason to distort beliefs here is instrumental: absent present bias, beliefs would be undistorted also before the exam (for $\beta = 1$, $\hat{R}_t^* = \hat{R}_0$). Note also that as the mental cost to self-delusion becomes arbitrarily small, this self-regulatory mechanism allows Sue to achieve the long-run optimal level of effort (as $\gamma \rightarrow 0$, $\hat{R}_t^* \rightarrow \hat{R}_0/\beta$ for $t = 1, 2$).

In sum, we obtain the following prediction.

¹³While our model presents a reduced form of the underlying psychological mechanism(s), this might for instance involve selective recall or selective attention (cf. [Bénabou and Tirole, 2002](#)), with the doer being unaware of the strategic selection, however. See also our related concluding discussion in [Section 6](#).

¹⁴Allowing for information arrival would complicate the model but can be incorporated. We abstract from it here to focus on the proposed behavioral channel, so any belief change is caused by the motive to overcome the self-control problem. Moreover, together with the fact that Sue’s planner has dynamically consistent preferences, it also conveniently implies that it is without loss of generality to have her choose beliefs once-and-for-all at the outset.

Main Prediction (Return Beliefs): *Sue’s expectation of the returns to her study effort*

(1a) is the higher the closer ahead is her exam, and

(1b) drops sharply after she took her exam.

What matters for this prediction is sophistication of the planner – it is qualitatively unaffected by naïveté of Sue as the doer. However, naïveté implies, over and above the made prediction, that Sue mispredicts her future effort, which affords a simple test of whether she indeed suffers from present bias.¹⁵

We would like to emphasize that the goal of our model is to offer but the simplest concrete formalization of our hypothesized mechanism (as highlighted in the above prediction), before investigating it empirically. While it should be clear that the main prediction is robust, as it does not depend on parametric case distinctions—e.g., it also obtains with costless belief distortion together with a lexicographic taste against self-delusion of the planner whenever indifferent—we consider any additional predictions that depend on parameter constellations or exact functional specifications as mostly suggestive for empirical exploration.

One such additional prediction seems natural and concerns the relationship between the extent of belief distortion and the extent of present bias. Sue’s belief \hat{R}_t^* increases in her present bias (i.e., decreases in β) unless she suffers from overwhelming present bias as the doer.¹⁶ Specifically, this is guaranteed if $\beta > 0.5$, a threshold safely below the available estimates (see [Augenblick and Rabin, 2019](#); [Cheung, Tymula, and Wang, 2021](#)).

¹⁵At the beginning of period 2, when she already has belief \hat{R}_2^* , naïve Sue would overpredict her subsequent effort under any “partial” naïveté in the sense of [O’Donoghue and Rabin \(1999\)](#). Earlier on, in period 1, she may however over- or underpredict her period-2 effort: while naïveté, as usual, works towards overprediction, her beliefs will subsequently become upwards-distorted, which works towards underprediction.

¹⁶The sign of $\partial \hat{R}_t^* / \partial \beta$, $t \in \{1, 2\}$, is negative if and only if $(0.5 - \beta)2\gamma < \kappa_t^2$, where $\kappa_1 = \beta\delta^2$ and $\kappa_2 = \beta\delta$. To see intuitively why this relation breaks down for small β , take the extreme case of $\beta = 0$: belief distortion then has no instrumental value, because such a myopic doer Sue would exert zero effort anyways.

4 Data Collection, Hypotheses, and Identification

4.1 Data Collection, Sample and Belief Measures

We collected the data in a repeated online survey of the students taking our first-semester microeconomics course at Humboldt-Universität zu Berlin, in the winter term 2015/16.¹⁷ The survey consisted of six waves, eliciting students’ beliefs about their study effort, grades and returns to studying at different stages in the semester cycle. We describe here its key features; further details are provided in Appendix B. Participation in the survey was voluntary and incentivized with a €10 completion payment, plus the chance (1:7) of winning an Amazon voucher worth €100. After the final wave of the survey, the data were anonymously matched with data from the university’s examination office.

The timeline of our survey is visualized in Figure 1. An important feature for our design is that any given student faces one of two different exam dates that were several weeks apart, namely February 23, 2016 (in exam period 1), and April 15, 2016 (in exam period 2). All students were required to commit themselves to one of the two dates by January 25, 2016 (exam registration) – a decision that students typically make with the goal of balancing their individual schedules of about six final course exams per semester. The students’ individual schedules are heterogeneous, as they depend on the program of study and year/semester of entry, as well as individual study progression and course choices. We started the first wave of our survey in mid-December 2015, and the final wave was completed in early May 2016. In our initial wave we had 214 respondents, which is about one half of the students who ended up writing the exam. Over the total survey period of around 18 weeks, 96 students dropped out of the survey.

A crucial part of our identification strategy is to have observations from students who participated in all six waves and who can be unambiguously assigned to one of the two exam dates. Our sample of interest therefore includes only the “stay-ons” who wrote the exam on the date they had registered for.¹⁸ This leaves us with a total of 84 observations: 60

¹⁷One author (Weizsäcker) gave the weekly lectures, two authors (König and Schweighofer-Kodritsch) held weekly class tutorials, and one author (Bönisch) conducted the survey without being involved in teaching. There were three further TAs who were not involved in this research in any way.

¹⁸Students who failed their exam on the first date could repeat the exam on the second date, and for students who initially planned to write the exam on the first date but then had to take the second date due

Figure 1: Survey Timeline

Notes: The figure visualizes the timeline of the survey comprising of six waves (W1–W6). Grey bars indicate the number of participants in each wave. First-exam takers write the exam between W3 and W4, second-exam takers between W5 and W6.

first-exam takers (group 1) and 24 second-exam takers (group 2). In Appendix A, we show that this (reduced) sample of 84 students does not significantly differ from other students who completed the first wave in terms of background characteristics elicited there. Moreover, the same is true when comparing the two groups of students that form our sample.

From wave 2 onwards, we elicited beliefs about the returns to studying. We asked students to give us an estimate of the percentage points they expect to achieve in their microeconomics exam for two hypothetical effort scenarios: (a) if they were to study for the exam for 20 hours in the 14 days prior to their exam date, and (b) if they were to study for 40 hours in the 14 days prior to their exam date. In a wave occurring after a student’s exam date, this question was adjusted to refer to the past; i.e., we asked what percentage of points a student thought she would have achieved if in the 14 days prior to her exam she had studied 20 hours, and similarly for the case of 40 hours. The numbers for the hypothetical effort scenarios were chosen based on the students’ own effort expectations: in wave 1, 20 and 40 hours are the

to proven illness, our return questions could be mis-interpreted, which is why we dropped these observations from our sample. For details, see Appendix B.3.

two tertiles (rounded) of responses to a question about own expected study effort during the 14 days prior to their exam date.¹⁹ Our return belief measure is the difference in the subjectively expected percentage points achieved in the exam between the two hypothetical effort scenarios. We denote this belief by r_τ^i for student i and wave τ .

Our second variable of interest, in addition to *return* expectations, is the students’ prediction of their own study *effort*, which allows to investigate our assumption of a self-control problem. Specifically, we also asked students how many hours they expected to study for the exam in the 14 days prior to it (with straightforward adjustment to refer to the past after the exam), corresponding to e_2 in the model. Summarizing our findings, we indeed find evidence of a self-control problem for students, via naïveté about and hence “overprediction” of their future study effort. In wave 3, shortly before the exam of group-1 students, these students on average predict their study effort to be 43.25 hours, while shortly after the exam, in wave 4, they report to have studied only for 38.69 hours. For group-2 students, we observe a similar pattern: in wave 5, they report an average prediction of 42.69 hours, whereas in wave 6 they report an average of 37.35 hours.²⁰ Confirming this pattern of overprediction, we also find that the students tend to overpredict the total number of course exams they would write: the average difference between their prediction at the initial wave 1, before any exams, and their report in the final wave 6, after all exams, is 0.24 for group 1 and 0.30 for group 2.²¹ Effort overprediction and exam overprediction exhibit a statistically significant positive correlation (0.248, $p = 0.025$).

4.2 Empirical Strategy and Hypotheses

As explained in the introduction, we deal with the possibility of correlated information shocks by exploiting the timing of the exam. Group-1 students take the exam seven weeks before

¹⁹The median response in wave 1 is 30. These aggregate statistics are the only information we received before the end of the survey and finalization of all grading.

²⁰The average overprediction in our data is 4.78, which is significantly different from zero at the 5-percent level. When calculating this average, we removed two students’ observations who reported more than 200 hours in the final study period (one per group). This implies that they would study more than 14 hours a day in each of their last 14 days before the exam, which we find implausible and constitutes extreme outliers by any standard.

²¹These are the numbers excluding the two students with “unrealistic” effort reports also here, for comparability. (Otherwise the numbers would be 0.25 for group 1 and 0.29 for group 2.)

group-2 students, whereby, at any given point in *calendar time*, the two groups are identical in terms of available information but differ in terms of *model time* (i.e., distance to exam), and hence in terms of how important self control is.

Define $s_t^i \equiv r_t^i - r_{t-1}^i$ as individual i 's belief revision between times $t - 1$ and t . Rational expectations imply that this revision has a zero expectation as of $t - 1$. Moreover, if information innovations (belief revisions) are i.i.d. within a sample of n people, then the group average $s_t = \sum_{i=1}^n s_t^i$ approaches zero with growing n . In our application, however, belief revisions are likely to have a common component due to common information: $s_t^i = \epsilon_t^i + \eta_t$, where only the first term is i.i.d., while the second is a common innovation. Under rational expectations, any such common innovation η_t shifts the sample's average. However, the difference between two groups' averages has this common component removed, hence $s_t^{G_1} - s_t^{G_2}$ still approaches zero ($s_t^{G_k}$ is group k 's average). Comparing our two groups, we can test whether expectations are rational against the alternative hypothesis of a systematic pattern over time, as predicted by our model.

Figure 2 illustrates the “literal” prediction of our theoretical model, which abstracts from information shocks, with calendar time (i.e., waves 2 through 6) on the horizontal axis and the agent's return beliefs at different moments in model time on the vertical axis. The figure illustrates how both groups progressively “build up” their return beliefs as their respective exam date approaches. Group 1 takes the exam at the first date, between waves 3 and 4, whereas group 2 takes the exam at the second date, between waves 5 and 6. Hence, they go through the same dynamic pattern of beliefs, but in a staggered fashion. At wave 3, group 1 is close to their exam, corresponding to $t = 2$ in the model, whereas group 2's exam is still distant, corresponding to model time $t = 1$. (Note here that group 1 starts relatively high already in wave 2, carried out right after the end of the exam registration phase, because of its temporal proximity to wave 3 and hence also group 1's exam.) At wave 4, group 1 is past their exam (without having learned their grades yet), corresponding to model time $t = 3$, whereas group 2's exam is still distant, corresponding to another version of model time $t = 1$ (the figure's notes explain the parameterization). At wave 5, group 2 is close to their exam, corresponding to model time $t = 2$, etc.

Common information may shift both groups' beliefs, however. In our statistical analysis,

Figure 2: PREDICTED RETURN BELIEFS OVER TIME

Notes: This graph depicts the model’s prediction of expected returns \hat{R}_t^* over the five waves (2 through 6) where this belief was elicited, for our two groups (group 1 in blue, and group 2 in red). To derive numerical predictions that take into account the different distances to the exam (e.g., in wave 2 both groups are at model time $t = 1$ but group 1 is much closer to their exam), we extend Section 3’s model to T pre-exam periods (days), which is straightforward. We then use actual days of the survey (see Figure 1), together with a discount factor of 0.95 per day.

we control for this by basically considering an upcoming exam as a treatment for which we have a control group. Specifically, we then let each group be the treatment group in waves where, according to our model, belief manipulation incentives are the strongest: wave 3 for group 1 and wave 5 for group 2. We take the respective other group as the control group and predict return beliefs to be higher for treatment than for control. We also predict that once the exam is written and there is no instrumental motive to distort return beliefs, they become undistorted. Hence, within each group we predict a drop in average beliefs in the wave immediately following this group’s exam, relative to the group that did not just write the exam.²² Our main hypotheses, concerning return beliefs, are summarized below.

²²More generally, students’ beliefs may be subject to systematic biases in updating that are independent of the instrumental motive we aim to test for. From this perspective, the control group serves as baseline, against which we compare updating under exam treatment, which intensifies the self-control problem.

Main Hypotheses (Return Beliefs):

- (1a) *In wave 3, the average return belief of group 1 exceeds that of group 2, and in wave 5, the average return belief of group 2 exceeds that of group 1.*
- (1b) *Between waves 3 and 4, there is a drop in the average return belief of group 1 relative to group 2, and between waves 5 and 6, there is a drop in the average return belief of group 2 relative to group 1.*

5 Results

5.1 Main Hypotheses

Graphical Illustration We begin the analysis with a graphical illustration of our key variable of interest: Figure 3 shows the dynamic pattern of mean return beliefs for our two groups. The figure covers waves 2 through 6, where the questions about returns were included in the survey. The blue and red lines represent the means of group-1 and group-2 students, respectively.

Even for each group in isolation, we observe that beliefs build up towards the exam, reaching their single peak at the wave immediately preceding it, and then drop right afterwards. Figure 3 quite closely resembles the illustration of the model’s literal prediction of Figure 2, remarkably so in fact for group 2.²³ Some more detailed features are not predicted by the simple model as such. First, in wave 4, group 2’s beliefs are slightly (though insignificantly) below those of group 1, where one may have expected the opposite because group 1 has no instrumental motive for distorting beliefs any more, while the motive may be at work for group 2 already, even a month’s time before their exam. Second, and relatedly, while group 1’s beliefs do drop right after the exam, they subsequently drop further, and even more sharply, before ultimately returning to a level similar to that in wave 4.

²³Appendix A’s Figure 4 shows box plots of return beliefs by exam group and wave period. While interquartile ranges are rather similar between groups and quite stable over time, our main hypotheses are qualitatively confirmed also in terms of the groups’ *median* return beliefs (though these do not exhibit an absolute increase over pre-exam waves as observed for *mean* return beliefs).

Figure 3: RETURN BELIEFS OVER TIME

Notes: Figure 3 plots mean return beliefs over waves 2-6 by group, blue for the earlier exam-takers of group 1 ($N = 60$), red for the later exam-takers of group 2 ($N = 24$). Error bars represent the standard error of the mean.

However, it is notable that both groups' beliefs reach similar peak levels before their respective exams, and the two groups' beliefs basically converge after each exam. The latter holds true in particular in the final wave 6. Although group 2 then still has not yet learned their grades, neither group has any instrumental distortion motive at this point (both are post-exam), and their beliefs largely coincide. In fact, the *overall* average return belief of the pooled sample in the final wave 6 is very similar to that in wave 2, when this belief was first elicited, albeit with a much reduced variance (means of 16.89 vs. 16.63, and variances of 94.84 vs. 64.28, in wave 2 vs. wave 6, respectively). This initial-final comparison is consistent with an unbiased prior and rational (Bayesian) updating from i.i.d. information – but the dynamic (diverging) patterns of the two groups in-between are inconsistent with it; instead, they are largely in line with the instrumental belief-distortion channel. Summing up this first graphical investigation, our simple model naturally misses some aspects of the observed patterns but it matches the key qualitative features of each group's return beliefs and supports our main hypotheses regarding the group differences rather well.

Regression Analysis: Hypothesis 1a Table 1 contains regression results that allow testing whether students whose exam is imminent have higher return beliefs than students whose exam lies in the more distant future, or in the past (Hypothesis 1a). We carry out every regression with and without control variables elicited in the initial wave 1.²⁴ Columns 1 and 2 report the corresponding results from regressing wave 3 return beliefs, r_3^i , on an *Exam* dummy indicating that the student takes the exam between waves 3 and 4 (here, meaning that she is in group 1). The *Exam* coefficient is positive, as predicted, but not significantly so. Running the corresponding regression for the second exam date – here, using r_5^i as the dependent variable and letting *Exam* equal one for group-2 students – also gives the predicted sign without significance (columns 3 and 4). A pooled regression that combines both data sets and includes a *Date 2* dummy (equal to one for group-2 students) to capture time-fixed effects produces a similar estimate on *Exam*, but with much smaller

²⁴These control variables are gender, semester of study, whether they take the microeconomics course the first time, their program of study (economics, business, other), age, their expected result (percentage score on their exam) and their expected effort (study hours during the fourteen days before their exam) as of wave 1.

standard errors, such that we obtain statistical significance (columns 5 and 6). These results are robust to including various controls, which we list in Footnote 24. The full regression results can be found in Appendix A’s Table 7.

*** p<0.01, ** p<0.05, * p<0.1

Regression Analysis: Hypothesis 1b To test for relative drops in return beliefs, we difference the beliefs between wave dates 3–4 and 5–6, respectively. For each individual we subtract the return belief in the wave occurring immediately before an exam date from the return belief in the wave occurring immediately after that exam date. We regress the resulting difference, $\Delta_t^i := r_t^i - r_{t-1}^i$ (for $t = 4$ and $t = 6$), on an *Exam* dummy indicating that the student’s exam immediately preceded wave t (in $t = 4$ it equals one for group 1, and in $t = 6$ it equals one for group 2). We run this regression again for each exam date separately and also for the pooled sample, in the latter case controlling for time-fixed effects via a *Date 2* dummy, all with and without the aforementioned control variables.

The results are summarized in Table 2, whereas the full results including all controls can be found in Appendix A’s Table 8. The *Exam* coefficient is negative throughout, indicating

that students who are “treated” in the sense that they recently wrote the exam ($Exam=1$) experience a drop in their return beliefs, relative to “untreated” students. This finding is again robust to including controls, and it is statistically significant for the pooled regression.

5.2 Robustness of Main Results

We here address what we consider the three main concerns regarding our findings: Endogenous selection into groups, group-specific exam information, and how the belief distortion observed in our microeconomics course relates to analogous data from another course.

Selection Due to university regulations, we could not randomly assign students their exam dates exogenously, nor incentivize them in some way. Hence, one might worry about endogenous selection of students into exam dates (corresponding to our two groups), such that it somehow generates the particular pattern observed. Though we could not think of any plausible selection condition that would produce the rather intricate dynamic pattern of return beliefs for *both* groups separately, we cannot rule out that one exists. However, in terms of the personal characteristics that we elicited in wave 1, we find that the two groups are balanced (see Appendix A’s Table 5 (a)), and this holds true also in terms of proxies related to academic ability and self-control – specifically, their expected and actual exam performance, how much they overpredict their study effort and how much they overpredict the total number of exams they would write that semester (see Appendix A’s Table 5 (b)). Probit regressions further confirm that none of these controls and proxies for ability and self-control are predictive of group membership, i.e., whether a student would write the exam at the first or second date (see Appendix A’s Table 6).

Regarding attrition, we note that the students who dropped out of the survey over time could reasonably be expected to experience *more* severe self-control problems than the students who managed to complete all six waves. This would suggest that the observed belief distortions about the return to study effort, based on the latter subsample, may well be underestimated.

Exam Information While the two groups of students wrote exams on the same course, their exams were not identical, of course. To the extent that our empirical confirmation of the predicted drop in return beliefs (Hypothesis 1b) stems from updating from the actual exam, group differences may arise by construction. However, information conditions were equalized across groups as far as possible, as each exam was made available to all course participants directly after it had been written. Moreover, we made all reasonable efforts to keep the contents and levels of difficulty of the exam questions identical.

In addition, our later survey waves asked the participants whether they knew the contents of the exam of the earlier date. Thus we are able to redo the corresponding regressions using only the subsets of the respective control group that knew the relevant exam (with pooled data). Despite the accordingly smaller number of observations – as a control group, group 2 reduces to 13 out of 24 for the first exam, while group 1 reduces to 16 out of 60 for the second exam – the results are robust to this variation: We obtain statistically significant estimates with the predicted sign (*Exam* coeff. -4.27, s.e. 1.81, without controls, and -4.50, s.e. 1.87, with controls, both significant at the 5%-level; see Table 9 in Appendix A for the full regression results).²⁵

Cross-Validation with Additional Course In addition to the microeconomics course, which we taught ourselves, the students also reported return beliefs regarding the introductory mathematics course, which most students take simultaneously to microeconomics. There are several reasons for why the responses about the mathematics course may be less reliable: most importantly, the survey waves were timed towards the exam dates in microeconomics, which differ from those in mathematics. Therefore, at the time of wave 3 the students who took the first mathematics exam were already one week into the 14 days period before the exam, and thus the timing relative to the exam is not “symmetric” across groups. Moreover, we have no hard information regarding which mathematics exam date students registered for or actually took, nor any grade information. Nonetheless, we use this data to carry out a similar analysis on the responses about the mathematics exams, and investigate whether the belief distortion that we find regarding the microeconomics course correlates

²⁵We also confirm Hypothesis 1a for this subsample, though the corresponding *Exam* coefficient is only marginally significant.

with a potential belief distortion regarding the mathematics course.

Performing regressions analogous to those above for our main hypotheses—here with 44 group-1 students and 19 group-2 students, based on self-reports in final wave 6—we find some further support for both hypotheses (for the full regression details, including controls, see Appendix A’s Tables 10 and 11). First, students that are just about to write the exam tend to exhibit higher return beliefs than students whose exam lies in the more distant future or in the past (i.e., for both exam dates), though this tendency is rather weak here and not statistically significant (even for the pooled sample). Second, return beliefs of students who have just written the exam decrease relative to their respective control group; this effect is statistically significant for the first exam date (1%-level) as well as for the pooled sample (5%-level). Notably, our controls once again leave estimated treatment effects unaffected.

*** p<0.01, ** p<0.05, * p<0.1

Most importantly, however, we find strong correlations between microeconomics and mathematics in all three key measures related to instrumental return belief distortion to overcome a self-control problem. These are (i) effort overprediction, as predicted effort in the wave immediately preceding the exam minus reported effort in the wave immediately succeeding the exam (wave 3 vs. wave 4 for group 1, and wave 5 vs. wave 6 for group 2), (ii)

“post-exam belief deflation,” as the drop in return beliefs subsequent to writing the exam ($r_3^i - r_4^i$ for group 1, and $r_5^i - r_6^i$ for group 2), and (iii) “pre-exam belief inflation,” as the gradual inflation of return beliefs in the period leading up to the exam ($r_3^i - r_2^i$ for group 1, and $r_5^i - r_4^i$ for group 2). Table 3 presents the results of regressing each of these individual measures for microeconomics on the same measure for mathematics, with and without control variables. Despite the smaller sample—only 52 students out of the 84 students in our main sample took the mathematics exam—the corresponding (partial) correlations are statistically significant, and they are all high, well above 0.5.²⁶ Again, including control variables hardly affects the estimates (see Appendix A’s Table 12 for the full results). This evidence is consistent with the argument that the fundamental reason for belief distortion in our model is a personal trait, present bias, which has similar consequences in both courses.

5.3 Further Results

Return Beliefs and Study Effort Our return belief elicitation concerns the difference between two hypothetical scenarios (40 vs. 20 hours of study effort). Our measure exhibits great variance, as can be seen from Figure 3, raising the question of how strongly it relates to actual behavior. To address this question we regress effort (expected or ex-post reported) on the return belief measure, as well as various controls. The results show a strongly significant positive correlation, supporting the validity of our belief measure as a basis for behavior (see Appendix A’s Table 13).

Belief Distortions, Present Bias, and Exam Performance An intuitive but theoretically not entirely straightforward hypothesis is that the amount of upwards distortion in return beliefs increases in the degree of present bias (decreases with β). The students’ effort overprediction provides a measure of their present bias, allowing to investigate also this hypothesis. We again consider both pre-exam return inflation and post-exam return deflation for belief distortion here, and we additionally investigate whether the same individuals who inflate return beliefs pre-exam also deflate post-exam.

²⁶We have 29 group-1 and 9 group-2 students who took the mathematics exam at the first date. For the second date these numbers are 7 and 7, respectively.

The correlation coefficients between these three measures for the pooled sample are all positive;²⁷ in particular, effort overprediction is positively correlated with both pre-exam belief inflation (correlation coeff. 0.342, significant at the 1%-level) and post-exam belief deflation (correlation coeff. 0.198, significant at the 10%-level). Moreover, there is a very high correlation between the two measures of belief distortion (correlation coeff. 0.548, significant at the 1%-level).²⁸

Finally, we note that if belief distortions were unrelated to self-control problems, we would expect students with stronger present bias to perform significantly worse on the exam. We therefore use effort overprediction as a measure of present bias and relate it to actual exam scores. While with a negative sign, the plain correlation is close to zero, equal to -0.083, and statistically insignificant. This is well in line with the motivational mechanism suggested here, namely that the students' self-control problem is at least partially resolved by distorting return beliefs. Of course, this is only suggestive, as present bias may be correlated with unobserved "natural" microeconomics skills.

6 Concluding Remarks

This paper provides evidence of systematic deviations from rational expectations about the returns to studying. A key feature of the analysis is that the test for rational expectations works without any observation on the *actual* returns to studying. The violation of the martingale property is enough to conclude that rational expectations are rejected. For natural settings such as ours, we show how to augment this basic test by a suitable control group, in order to rule out that the effect is driven by correlated information. Thus, we provide a method that extends its applicability.

Of course, the value of finding such a violation of rational expectations rests on the behavioral mechanism that one desires to test (as does, in this paper, the entire empirical

²⁷We again exclude the two students (one per group) with impossible effort reports of more than 200 hours, though the findings do not hinge on that; see footnote 20.

²⁸Splitting the sample by group yields qualitatively similar results, though for group 1 all correlations are weaker than for group 2 (indeed, for group 1, effort overprediction is hardly correlated with the belief distortion measures, while the latter two remain highly and significantly correlated); and a similar picture emerges when running regressions, including controls (see Appendix A's Table 14).

design). Here, the particular dynamic pattern of beliefs we observe is predicted by the motivational incentives that arise with self-control problems: the importance of self-control increases as the exam gets closer in time and vanishes after the exam, and belief deviations follow exactly the same pattern.

The paper thereby contributes to the literature on self-control, which has mostly focused on extrinsic commitment opportunities (for a review see [Bryan, Karlan, and Nelson, 2010](#)) or intra-personal equilibrium strategies employing self-punishments and self-rewards (in a non-cooperative game between the multiple selves with conflicting preferences; e.g., see [Bernheim, Ray, and Yeltekin, 2015](#); [Kodritsch, 2015](#)). Both of the latter are effective only under a high degree of sophistication, however; by contrast, empirical evidence suggests that people instead tend to be rather naïve ([Augenblick and Rabin, 2019](#); [Breig et al., 2020](#); [Le Yaouanq and Schwardmann, 2022](#)). Indeed, we confirm this also in our sample, where students significantly over-estimate their future study effort.

Our simple planner-doer model moves the sophistication to a time consistent planner, as a way of reconciling naïveté with successful self-control. The doer has a present bias and may well be naïve, but she is sub-consciously regulated by the planner who sophisticatedly employs belief manipulation. The model thus also captures the notion of willpower in a very simple and intuitive manner, namely in terms of the mental costs of such belief manipulation (cf. [Mischel, Shoda, and Rodriguez, 1989](#)). We therefore consider its further development in terms of (other) distinct implications and broader applicability a promising avenue for future research.

We have empirically tested (and confirmed) the predictions of this simple model only against rational expectations. Despite our robustness and further supporting results, there are rather obvious data limitations, largely due to our study’s natural setting and resulting constraints. Alternative explanations can surely be constructed, and indeed, we consider this paper’s main contribution a conceptual/methodological one. However, what is remarkable about the mechanism proposed is its parsimony/simplicity in explaining the dynamic belief pattern of *both* groups, while also explaining related experimental findings, by combining two leading insights from behavioral economics: present bias and malleable beliefs. For instance, while the drop in return beliefs post-exam could be ex-post rationalization of low study

effort, our model actually explains this part of the dynamic pattern of beliefs the same way as it explains why they are inflated pre-exam, on which ex-post rationalization is silent. The explanations differ then only in whether post-exam return beliefs are pessimistic or realistic, but our study’s aim is not at all to dismiss the psychology of ex-post rationalization (or of emotions-management more broadly), but to develop and test a hypothesis about the psychology of self-control. Also, while we cannot rule out selection on unobservables (of course), we could also not think of any alternative theory that is based on equally well-established principles and would explain our findings upon allowing for some such selection.

Predicting and measuring belief dynamics is a novel area of research. An important aspect in it for policy purposes is how people select, process and recall information. Given the purpose of this research as well as its empirical setting, we employed a reduced form model of belief formation, without specifying the psychology of how exactly students arrive at and maintain distorted return beliefs – in particular, whether by motivated processing of information ([Sharot, Korn, and Dolan, 2011](#); [Lobeck, 2022](#); [Möbius, Niederle, Niehaus, and Rosenblat, 2022](#)) or by motivated memory ([Chew, Huang, and Zhao, 2020](#); [Zimmermann, 2020](#); [Roy-Chowdhury, 2023](#)). In the presence of self-control problems or other behavioral deviations from the standard model, the short- and long-run psychological and behavioral effects of information are far from obvious: for example, in our model, additional information may help by making the planner more informed (she may have a false prior expectation; relatedly, see [Breig et al., 2020](#)) but it may also increase her costs of distorting beliefs and thereby make self-control harder (relatedly, see [Huck et al., 2018](#), and also [Roy-Chowdhury, 2023](#)).

Altogether, we see this paper’s contributions in (i) proposing as well as formalizing the idea that beliefs are an instrumental means of self-control, and highlighting the relevance of return beliefs; in (ii) designing a dynamic empirical approach repeatedly eliciting return beliefs via two fixed counterfactuals and exploiting natural variation over time as well as between groups in the importance of self-control for identification; and in (iii) presenting supportive evidence for the hypotheses derived from our model, using this approach on a convenience field sample. Thus, we hope to inspire future research that develops the proposed link and approach further, both theoretically and empirically.

Appendix

A Additional Tables

A.1 Summary Statistics and Selection Analysis

Table 4 compares the students from our main restricted sample with all others who participated in wave 1. There are no significant differences between these two groups in terms of gender, study program, first-time takers of the course, number of semesters of study, or age (all except semester and year of birth are either one or zero).

Table 4: SUMMARY STATISTICS – MAIN SAMPLE VERSUS OTHERS

	main sample		others in wave 1		diff	t-stat
	mean	sd	mean	sd		
male	0.43	0.50	0.51	0.50	0.08	(1.13)
economics	0.45	0.50	0.34	0.48	-0.11	(-1.68)
business	0.44	0.50	0.52	0.50	0.07	(1.07)
other program	0.11	0.31	0.15	0.35	0.04	(0.82)
first time micro semester	0.79	0.41	0.75	0.43	-0.03	(-0.54)
year of birth	1.90	1.48	2.22	2.11	0.31	(1.18)
Observations	84		130		214	

*** p<0.01, ** p<0.05, * p<0.1

Table 5 (a) shows that there are also no significant differences in these background characteristics between groups 1 and 2.²⁹ The table’s second panel (b) compares the two groups by exam score (percentage of points achieved), expected exam score at wave 1 as well as at the respective pre-exam wave, expected effort pre-exam minus reported effort post-exam (effort “overprediction;” pre-exam is wave 3 for group 1 and wave 5 for group 2, post-exam is the wave immediately thereafter in each case), and initially (as of wave 1) expected total number of course exams that would be written that semester minus ultimately reported

²⁹Regressing a group-1 dummy on background characteristics results in failure of significance of the F-statistic, indicating that our observable background characteristics cannot jointly explain selection into these groups.

Table 5: SUMMARY STATISTICS BY TREATMENT GROUP

(a)

	group 1		group 2		diff	t-stat
	mean	sd	mean	sd		
male	0.45	0.50	0.38	0.49	-0.07	(-0.63)

Observations	60		24		84	

*** p<0.01, ** p<0.05, * p<0.1

(b)

	group 1		group 2		diff	t-stat
	mean	sd	mean	sd		
achieved points (in %)	58.94	18.55	57.63	18.51	-1.31	(-0.29)
exp. result (wave 1)	72.03	11.53	69.96	11.56	-2.08	(-0.73)
exp. result (pre-exam)	67.12	14.63	67.22	14.01	0.10	(0.03)
effort overprediction	4.56	17.35	5.34	21.05	0.79	(0.17)
exam overprediction	0.24	1.28	0.30	1.15	0.07	(0.22)
Observations	59		23		82	

Removed one observation per group with unrealistic effort reports (> 200 hours).

Exam overprediction corresponds to the difference in the number of planned (wave 1) and written (wave 6) exams. Effort overprediction is defined as the difference between expected effort in the pre-exam and post-exam wave.

*** p<0.01, ** p<0.05, * p<0.1

number (as of wave 6). Again, groups appear indistinguishable, including even in terms of actual exam scores.³⁰

We use Probit regression analysis to further examine selection into the first or second exam date, i.e., group; in particular, whether it depends on proxies of unobservable characteristics, such as ability or self-control. The actual exam score is a direct measure of ability, whereas expectations about future exam performance reflect beliefs about own ability (under standard assumptions). The difference between ex-ante expected and ex-post reported effort, and that between the ex-ante expected and ex-post reported total number of course exams

³⁰Grading exams was done by class tutors who were not involved in this research.

written measure self-control. Our Probit regression results in Table 6 confirm that students' choice of exam date (group membership) is independent of background characteristics and these proxies.³¹

Table 6: PROBIT REGRESSIONS

Robust S.E. in parentheses.

Marginal Effects are calculated as the average of the marginal effects at each observation.

*** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$

³¹The Probit results are robust to excluding the two observations with unrealistic effort reports.

A.2 Main Hypotheses

Figure 4 shows box plots of return beliefs over exam groups and waves 2-6. The upper hinge of each box represents the 75th percentile, the lower hinge the 25th percentile, and the line the median.

Here we show the full regression tables, including various control variables, underlying Tables 1 and 2 in the main text, in Tables 7 and 8, respectively.

Tables 10 and 11 present the full regression results regarding our two main hypotheses for the data on the introductory mathematics course. Table 12 presents the full regression results linking belief distortion in microeconomics and in mathematics, extending Table 3 from the main body of the paper; due to the particular smaller subsample, we had to exclude even some of controls that are not course-specific (all 52 students in the sample are in economics or business, 51 of them take the microeconomics exam for the first time, and 50 of them are in their first semester of study).

A.4 Further Results

In Table 13, columns 1–3, we report regressions of expected effort (resp., ex-post reported effort) during the 14 days before the exam on return beliefs, where we pool all five waves for which we have data. We find our measure of expected returns economically validated: Students who believe the returns to studying to be higher, according to the hypothetical scenario of our survey question, also expect to study more (resp., report to have studied more).

The first column’s regression includes only a group dummy indicating when the student wrote the exam and our standard set of controls, the second column’s regression adds a variable indicating self-reported importance of the grade for one’s career (ranging from 1 for unimportant to 6 for very important), and the third column’s regression adds wave dummies (omitting wave 2).³² In column 4, we drop all observations from waves 2 to 5: The positive statistical relation between effort and expected returns holds when using ex-post exam measures only (wave 6); though it is not statistically significant with this smaller set of observations, this turns out to be due to including control variables;³³ in a regression without controls, it remains statistically significant (coeff. 0.416, S.E. 0.198, $p < 0.035$).

Table 14 shows full regression results for the correlations between effort overprediction, as a measure of present bias (assuming similar naïveté), pre-exam return belief inflation and post-exam return belief deflation. It shows these are all positively correlated, while only the positive correlation between the latter two measures of belief distortion is statistically significant, and it is so at the 1%-level.

³²We exclude two students’ observations here, which were extreme outliers, as explained in footnote 20. Including them has essentially no effect, except for marginally increasing the standard errors on the estimated return coefficient.

³³The only significant control variable here is gender: Women expect to study and report to have studied almost 8 hours more than men (coeff. 7.78, S.E. 3.851, $p < 0.05$).

B Panel and Sample Description

This appendix describes the dataset in detail – first its main component, the dynamic online survey, then the additional administrative data. Based on this description, we make explicit how we define our main sample.

B.1 Survey Panel

We conducted our survey in six waves, starting in December 2015 and ending in May 2016. Participants were informed (and also reminded) of each wave in advance through the online course portal, and sent an individual link via email for each wave. Upon opening the link they could respond online to the survey questions (e.g., using a smartphone). Failure to respond to a given wave meant dropping out from the survey (i.e., from all subsequent waves). All responses remained and still remain anonymous. Moreover, we had no access to any of this data until all grades had been finalized (except for the tertiles of expected study effort in wave 1, so we could construct our hypothetical scenarios). Table 15 gives an overview of what information we gathered when, and from how many participants. We invited participants to collect their payment for completion of the survey on May 3 and May 4, 2016. This payment consisted of 10 Euros in cash, plus a 1:7 chance of winning an Amazon voucher worth 100 Euros. This lottery was resolved on May 2, 2016.

Figure 5 provides a screenshot of our main question (in its original German version) regarding return beliefs, described in Section 4.1.

Figure 5: Screenshot of Main Question

Mikroökonomie Umfrage 2. Welle

0% 100%

• Mit welcher Prozentzahl der maximal erreichbaren Punkte würden Sie bei Ihrer Mikroökonomie-I-Prüfung rechnen, wenn Sie dafür in den letzten 14 Tagen vor dem Termin insgesamt (a) 20 Stunden beziehungsweise (b) 40 Stunden lernten?

(a) Bei 20 Stunden Lernen in den letzten 14 Tagen erwarte ich Prozent der Punkte.

(b) Bei 40 Stunden Lernen in den letzten 14 Tagen erwarte ich Prozent der Punkte.

ⓘ Achtung: Diese Zahlen stellen lediglich hypothetische Möglichkeiten dar und sind in keiner Weise als Empfehlung zu verstehen.

* We adopted the patience and risk tolerance measures from the preference module of [Falk, Becker, Dohmen, Huffman, and Sunde \(2016\)](#), and we added our own similarly formulated item on time-consistency, namely “Do you generally keep your resolutions?”

** This was also asked about a parallel mathematics course for which the two exam dates were February 16 and April 13; we have no hard data on this course whatsoever, in particular no registrations from the examination office or exam scores.

B.2 Course and Exam Organization, and Administrative Data

Below we provide information regarding course and exam organization:

- Examination periods and dates: Following the end of classroom teaching, there are two examination periods, and every course is examined once in each period. Each examination period lasts for two weeks. In our case the first ended on February 26, and the second on April 15.
- Exam registration and regulations: Students could register from January 1 through January 25. Any student not registered for either of the exam dates after this period

could not take the course’s exam. Registered students could withdraw from their exam until three working days prior to it, and then could not take the course’s exam (at either date). Students registered for the first exam who either supplied a sick note to the examination office for this date or failed the exam could register and then take the second exam.

- Microeconomics exam: The exam dates for our Microeconomics I course were February 23 (between waves 3 and 4) and April 15 (between waves 5 and 6). We published the first exam in the online course portal on March 4 (between the exam and wave 4) and the second on April 21 (between the exam and wave 6). Solutions were never provided. We released the grades for the first exam on March 17 (between waves 4 and 5) and offered exam inspection—a requirement for every exam—on April 6 (between waves 5 and 6). Release of the grades for the second exam and exam inspection took place only after the end of the survey.

The following data from the examination office were anonymously matched with our survey data. (Only for the microeconomics course; we had no access to official data for the mathematics course.)

- Exam registrations as of Feb. 9 (1 or 2 or missing).
- Exam registration lists for each exam date, as of a few days prior (in or out).
- Point scores for each exam date (0-90).

B.3 Sample Definition

Our two groups are defined as follows.

- Group 1:
 - Completed the entire survey (all six waves).
 - Took the exam at the first date, and not at the second date.

- Registered for the first exam with the examination office as of Feb. 9, or else were one of the two students not registered for either exam date as of Feb. 9, but nonetheless on the registration list for the first exam.
- Group 2:
 - Completed the entire survey (all six waves).
 - Took the exam at the second date, and not at the first date.
 - Registered for the second exam with the examination office as of Feb. 9, or else were one of the two students registered for the first exam date as of Feb. 9, but already in wave 3, which took place before Feb. 9, reported in our survey that they would take the exam at the second date.

B.4 Data Protection Concepts

B.4.1 Data protection letter sent to the university administration

We would like to carry out a study of studying behavior with the students in Microeconomics I. We are interested in the students' responses regarding their planned study effort and their expectations regarding grades (please find attached the survey questions). Additionally, we will collect background information as is usual in such surveys (e.g., gender and age).

Participation in the study is voluntary. We commit ourselves to not having any access to the data until all grading is officially finalized. Data will be externally collected and stored by our student assistant Felix Bönisch, and he will make them accessible to us after the final grading. The survey responses can therefore neither affect the design nor the grading of exams.

After grades have been officially awarded, we plan to match the survey data with the respondents' grades in an anonymized manner. To this end, we will use an encryption method that, at no point in time, allows to identify grades and survey responses with the corresponding students—neither by Mr Bönisch

nor by us. The encrypted matching of the data works as follows: we will send Felix Bönisch a list assigning each student number a key, where different student numbers are assigned the same key—based on “equivalent” grades—, and Mr Bönisch will then send the list back to us such that student numbers are replaced with the corresponding survey answers. Hence, these responses cannot be linked to student numbers.

Finally, we would like to stress that the careful handling of data protection issues is in our own best interest. Only by doing so can we obtain a large number of participants and credible survey answers, which is essential for the quality of our research.

Prof. Georg Weizsäcker, Sebastian Schweighofer-Kodritsch and Tobias König;
Berlin, December 4, 2015

B.4.2 Data protection announcement to participants

Dear students,

Thank you very much for your willingness to participate in this survey. Your sincere responses will make an important contribution to human behavioral research. This is to assure you that your responses are anonymous. Our procedure has been approved by the School of Business and Economics of Humboldt-Universität zu Berlin, and, moreover, your anonymity is also in our best interest for the quality of our research.

1. During the entire survey period, i.e., until all grades have been finalized, none of the researchers involved will have access to the data collected. Until then, these will be externally collected and stored. This rules out any influence of participants’ survey responses on exam design and grading.
2. The questions that we will ask you are innocuous. Apart from background information commonly asked in surveys, they relate to your expectations and your study behavior.

3. The use of an encryption mechanism in the data transmission (as mentioned in item 1, this will take place only after grades have been finalized) guarantees that grades and survey responses can never be identified with a survey participant.

In case you have any questions about the details of the study, you can reach us at any time via email to mikro.umfrage@gmail.com, where we are happy to respond as quickly as possible.

Kind regards,

Prof. Georg Weizsäcker.
