The Stress of Having A Single Monetary Policy in Europe

Abstract

This paper estimates forward-looking Taylor rules for the euro area. Using the asymmetries in inflation and cyclical output developments across countries, we investigate the adequacy of the single monetary policy for each of the European Monetary Union (EMU) member countries. Notable differences emerge across the countries. Taking a euro area perspective, we also show that it depends upon the underlying country weighting scheme in the monetary decision process of the ECB whether or not there has been a synchronisation of business and inflation cycles among the EMU member countries over the years. Finally, we produce an estimate of the actual policy weights the ECB has implicitly attached to each of the member countries. Developments in small member countries have received more than proportional weights in actual monetary policy decisions of the ECB.

JEL Code: C22, E52, E58.

Keywords: Taylor rule, monetary policy, ECB, stress, business cycle synchronisation.

1 Introduction

A topic regularly discussed amongst ECB watchers is the cost for the euro area countries of having a common monetary policy.¹ A single monetary policy almost by definition implies that policy will not be appropriate for all member countries at the same time. The larger the difference between the actual monetary policy and the monetary policy preferred by individual member countries, the more likely it is that the ECB will be under political pressure. To our knowledge, Clarida et al. (1998) were the first to associate this difference to what they call *monetary stress* and—in their case—use it to analyse the causes of the 1992/93 crisis of the European Monetary System (EMS).² Hence, stress in a monetary system occurs when—for whatever reason—a central bank is unable to set its policy instrument optimally.

In this paper, we follow up on this and provide monetary stress indicators for the euro area. Their evolution over time will supply important information concerning the adequacy of the single monetary policy for each of the EMU member countries. Furthermore, it allows us to construct a single indicator for business and inflation cycle synchronisation in the euro area as relevant for the monetary authorities. In this way we shed light on the question whether the euro area is indeed a self-enforcing optimal currency area and, at the same time, get a feeling for the country weighting scheme implicitly used by the ECB Governing Council in their monetary decisions. Following the work of Sauer and Sturm (2003, 2007), we use a state-of-the-art Taylor rule framework which is both forward-looking and based upon real-time information for this.

Using market expectations with respect to economic growth and inflation, we first of all conclude that stress levels differ considerably across the EMU member countries. Furthermore, under the assumption that the ECB takes a purely European perspective, we do not find that business cycles have been converging since the adoption of a common monetary policy by the ECB. In other words, when the ECB implicitly weighs participating countries according to their economic size, there is no evidence that the overall cyclical stress in the euro area has declined over time. However, according to, e.g. Berger (2006) the misrepresentation of economic size in the voting distribution of

¹Of course, there are also benefits associated to having a single currency. In this paper, however, we fully concentrate upon (part of) the cost side.

²Following the literature on foreign exchange markets and central bank intervention in which the term “exchange market pressure” plays an important role, another way to label this difference would be “interest rate pressure” or “monetary market pressure” (see e.g. Weymark, 1996, Tanner, 2006, and Van Poeck et al., 2007). However, in line with Clarida et al. (1998), we will henceforth label this difference “country-specific monetary stress”.

the ECB Governing Council is quite large. When we take a more political-oriented approach in which smaller member countries receive a weight larger than suggested by their economic size our previous conclusion changes and business cycles have become more synchronised over time.

Hence, the crucial question is which implicit weighting scheme is more relevant in practice? It is difficult to answer this question conclusively, but when we assume that the burden of the common monetary policy is over time evenly distributed across its member countries, especially the larger countries appear to have received a relatively small political weight, i.e. relative to their economic size. This implies a relatively large weight for the smaller economies in EMU monetary policy decisions. Also in such a scenario, business cycles tend to have become more synchronised over time.

This paper is organized as follows. The next section describes the way in which we construct our monetary stress indicators. Section 3 discusses the data in some detail, while section 4 presents our empirical results. After reporting our Taylor rule estimates for the euro area, we distinguish between a country-specific point of view (section 4.3) and an area wide perspective (section 4.4). Section 4.5 discusses the main findings and the final section offers some concluding comments.

2 Theoretical framework

2.1 Forward-looking monetary decision rule

Taylor (1993) established a relationship between the central bank interest rate and two indicators: the deviation of inflation from its target and the output gap. The Taylor rule interest rate is generally seen as a benchmark interest rate for actual monetary policy.

When using so-called Taylor rules to analyse the appropriate stance of monetary policy, it is important to take a forward-looking perspective. It is generally recognised that it will take several quarters for a policy change today to have its full-blown effect on the real economy and actual inflation rates. Hence, instead of focusing too much on today's inflation rate, the central bank is likely to put substantial weight on expected future developments in their decision-making process. Indeed, when exploring different ECB Taylor rules for the euro area, Sauer and Sturm (2003, 2007) conclude that only forward-looking specifications (by either taking expectations derived from surveys or assuming rational expectations) give estimated Taylor rules in line with both theoretical models and communicated behaviour of the ECB itself. Similar conclusions are drawn by Castelnovo (2007) and

Gorter et al. (2007). Hence, we explore forward-looking Taylor rules based on the idea that in order to ensure medium-term price stability, the central bank interest rate seeks to keep expected output and inflation fluctuations at their target rates.

In our formulation, real economic developments are proxied by growth rates instead of output levels, as is more common in the Taylor rule literature. Under the assumption of constant potential output growth, this implies that instead of the level of the output gap, we include the expected change in the output gap. To underline this difference, we therefore label our estimated reaction function as one of the “modified” Taylor rule. For instance, Walsh (2003) and Geberding et al. (2004) have argued that such a “speed limit policy”, or “difference rule”, performs quite well in the presence of imperfect information about the output gap. Given that output gaps are notoriously difficult to measure and tend to be revised substantially over time, this appears quite plausible. Growth rates, on the other hand, are much less prone to data revisions. Secondly, the use of growth cycles has the advantage that they in general have a clear lead over classical cycles. Furthermore, most theoretical models abstract from long-run growth. When allowing for trend growth, it is possible to specify Taylor rules in terms of output growth rates. Finally, expectations and forecasts are normally formulated in terms of growth rates and are therefore readily available. Any deviations of the expected inflation and growth rates from their targets will induce the central bank to adjust the interest rate.

The formula for the modified Taylor rate $i_{j,t}^*$ is as follows:

$$i_{j,t}^* = \alpha_j \Delta \bar{y}_{j,t} + \bar{\pi}_{j,t} + \beta_j (E_t \pi_{j,t+k} - \bar{\pi}_{j,t}) + \gamma_j (E_t \Delta y_{j,t+k} - \Delta \bar{y}_{j,t}), \quad (1)$$

where j denotes the country and $E_t x_{j,t+k}$ refers to the expected value of variable x in k months time based on information at time t . If the short-term interest rate is above the modified Taylor interest rate, it indicates that monetary policy is more restrictive than one would expect based on anticipations of inflation and output growth. If the actual interest rate is below the modified Taylor rate, it indicates that monetary policy is more expansionary than the inflation and economic growth expectations would suggest.

The first two terms define the time-invariant neutral nominal interest rate in country j , which corresponds to the interest rate that would prevail if all prices were flexible. Woodford (2003) refers to this rate as the Wicksellian natural rate of interest. Put more practically, the neutral interest rate is equal to the nominal interest rate that would prevail if inflation is at target and output growth equals its trend rate. In Equation (1), it is the sum of the

neutral real interest rate in country j and the inflation target. In line with Woodford (2003), Laubach and Williams (2003) and Garnier and Wilhelmsen (2005), we assume the neutral real interest rate to be a linear function of the trend growth rate of expected real GDP in country j , $\Delta\bar{y}_{j,t}$.

The last two terms in Equation (1) are the feedback terms, which prescribe the central bank how to adjust its operating target over time whenever the expected inflation gap ($E_t\pi_{j,t+k} - \bar{\pi}_{j,t}$) or the expected change in the output gap ($E_t\Delta y_{j,t+k} - \Delta\bar{y}_{j,t}$) deviate from zero. The more expected growth exceeds trend growth, the higher the modified Taylor interest rate will be. In the same way, the more expected inflation exceeds its target, the higher the Taylor interest rate will be. Hence, the coefficients β and γ are the weights given by the central bank to deviations from the inflation and growth targets.

Especially since the early 1990s, it is in practice commonly observed that central banks worldwide tend to move policy interest rates in small steps without reversing direction quickly. To capture such interest rate smoothing, the previous equation is viewed as the mechanism by which the target interest rate, $i_{j,t}^*$, is determined. The actual interest rate $i_{j,t}$ adjusts only slowly to this target according to

$$i_{j,t} = \rho_j i_{j,t-1} + (1 - \rho_j) i_{j,t}^* + v_t, \quad (2)$$

where ρ_j is the smoothing parameter, v_t the error term and $i_{j,t}^*$ is given by Equation (1). Some recent papers argue that the observed inertia in interest rates may also be explained by serially correlated error terms in the policy rule, which represent omitted shocks to policy behavior, like financial crises (see for example Rudebusch, 2002):

$$v_t = \delta_j v_{t-1} + \varepsilon_t, \quad (3)$$

where δ_j is the serial correlation parameter and ε_t is an independent identically distributed error term. Following English et al. (2003) we combine the partial adjustment model and the serial correlation model to obtain a nested empirical Taylor rule model that consists of Equations (1), (2) and (3).

2.2 Monetary stress indicator

As the ECB has to take into account developments on the aggregate European level, asymmetries in inflation and GDP developments across countries will generate differences between the actual optimal interest rate and the optimal interest rate that would have resulted if national central banks were able to respond to national inflation and GDP growth. We call this difference *country-specific monetary stress*,

$$S_{j,t} = i_{EA,t}^* - i_{j,t}^*. \quad (4)$$

It is defined as the gap between the optimal area-wide interest rate, $i_{EA,t}^*$, and the optimal interest rate that would prevail in country j , if it was able to follow a country-specific interest rate policy, $i_{j,t}^*$. A negative value for $S_{j,t}$ implies that actual monetary policy of the ECB for country j is more accommodative than what could be expected using country-specific data. If, on the other hand, $S_{j,t}$ is positive, actual monetary policy appears too tight for country j .

The main problem related to the calculation of country-specific stress is that national monetary policy cannot be observed in the 1999-2006 period, i.e. the period under investigation. In theory, an optimal monetary policy rule for a country can be obtained from the minimisation of an intertemporal loss function (over expected future deviations of some target variables from their target levels) subject to the current state and the structure of the economy. Ball (1999) and Woodford (2003, Ch. 7) show that the resulting reaction coefficients are a function of both, structural and preference parameters. The former relate to how the economy works, whereas the latter reflect the relative weights of the target variables in the central bank's loss function.

In implementing this concept, Flaig and Wollmershäuser (2007) take the optimal monetary policy rule to correspond to the policy rule that was adopted by the country in the pre-EMU period. They thereby take an extreme position. Besides keeping the structural parameters constant over time and country-specific, they also assume that the euro was forced upon the participating countries and that each individual nation would prefer a central bank with a similar behaviour as its own before the establishment of the Monetary Union. Hence, they also keep the preference parameters in the policy rule constant over time and country-specific.

We, on the other hand, assume that all EMU member countries voluntarily decided to participate, thereby signalling that in principle the institutional set-up of the ECB—and thereby the preference parameters as implied by the ECB—is preferred over the situation prevailing before the euro. Furthermore, we assume that the euro area economies function in rather similar ways, i.e. their structural parameters are very much alike. From this follows that national central banks would implement a similar policy rule as the ECB, if they had the choice to do so, implying that we only need to estimate the parameters of the ECB reaction function using aggregate euro area data

over the actual ECB operating period. Thus, stress can be computed as

$$\begin{aligned}
S_{j,t} &= [\bar{\pi}_{EA,t} - \bar{\pi}_{j,t}] + \\
&+ [\hat{\alpha}_{EA}\Delta\bar{y}_{EA,t} - \hat{\alpha}_{EA}\Delta\bar{y}_{j,t}] + \\
&+ [\hat{\beta}_{EA}(E_t\pi_{EA,t+k} - \bar{\pi}_{EA,t}) - \hat{\beta}_{EA}(E_t\pi_{j,t+k} - \bar{\pi}_{j,t})] + \\
&+ [\hat{\gamma}_{EA}(E_t\Delta y_{EA,t+k} - \Delta\bar{y}_{EA,t}) - \hat{\gamma}_{EA}(E_t\Delta y_{j,t+k} - \Delta\bar{y}_{j,t})], \quad (5)
\end{aligned}$$

where $\hat{\alpha}_{EA}$, $\hat{\beta}_{EA}$ and $\hat{\gamma}_{EA}$ are the point estimates of the ECB reaction function.

In the above equation, the first two terms in brackets reflect what we label structural stress ($S_{j,t}^{struct}$), whereas the last two terms in brackets are related to cyclical stress ($S_{j,t}^{cyc}$), i.e. to asynchronised short-run movements in inflation and growth expectations. Structural stress is defined as the difference between the estimated neutral interest rate for the euro area and the implied neutral interest rate for the country in question. As Equation (5) shows, we split up the neutral nominal interest rate in the neutral real interest rate (which is a function of the trend growth rate) and the inflation target. From this follows that the difference between the neutral nominal interest rate for the euro area and that for a specific country is due to both, a long-run inflation differential and a long-run growth differential.

2.3 Limits

It is quite evident that our counterfactual hinges on a range of assumptions, which require some more comments. In the counterfactual scenario a member country, which decides to leave the monetary union, sets its policy rate independently in an environment of flexible exchange rates by following the same policy rule as the ECB. The assumption that structural parameters are very similar across euro area countries implies that asynchronised business cycles can only be explained by asymmetries of (policy and non-policy) shocks across countries. A recent paper by Jondeau and Sahuc (2005) gives support to this assumption. Using a fully micro-founded and estimated multi-country model of the euro area, the paper reveals that structural differences in the behavior of private agents are not empirically relevant sources of business cycle heterogeneity across core countries of the euro area. They rather find that differences in actual business cycle developments are mainly due to similar types of shocks affecting the economies at different times. A similar conclusion is drawn by Giannone and Reichlin (2006).

The assumption that national central banks would implement a similar policy rule as the ECB—if they had the choice to do so—leads to a biased estimate of the true level of country-specific stress for most of the EMU

member countries at least for two reasons. On the one hand, a strong motive for participating in the monetary union actually was (and still is) the move to a more independent and thereby more credible central bank. This did not only apply for most Southern European countries, which were in this way able to lower both their interest rates as well as their inflation rates substantially, but also for a country like Finland. The way we construct country-specific stress assumes that these countries would have been able to gain the same amount of credibility as the ECB, if they had decided to remain outside the EMU. However, and more realistically, a less credible national central bank would be forced to change policy rates more than a credible central bank (like the ECB) when confronted with the same shock. These higher reaction coefficients (i.e. $\beta_j > \beta_{EA}$ and $\gamma_j > \gamma_{EA}$) lead to—in absolute sense—larger country-specific stress levels. Hence, our stress estimates underestimate the true level of country-specific stress (credibility bias).

On the other hand, the counterfactual assumes that the national central bank reacts to growth and inflation expectations, which are conditional on the counterfactual interest rate policy. However, it is clear that the observed expectations are conditional on the current state of the economy, and by this on the impact of the factual interest rate policy of the ECB on the member country. To assess the resulting bias of our stress measure, let us suppose that the individual countries are hit by a sequence of non-policy shocks, which are independent of the monetary regime, and that these shocks are uncorrelated across countries. Let us further consider a country whose weight in the ECB's monetary policy decision process is clearly less than one, implying that country-specific movements in growth and inflation expectations are not fully taken into account. The factual interest rate policy of the ECB will only partly contribute to a stabilisation of macroeconomic developments in that country. As in the counterfactual scenario the national central bank's ultimate goal is to stabilise national cyclical movements in inflation and output, this would lead to more stability as compared to what we actually observe when the country participates in a monetary union. Hence, the counterfactual interest rate policy in the individual country with an independent monetary policy will normally be less pronounced and our stress measure will overestimate the true stress (stability bias).

Of course, an exact quantification of the two opposing biases would require a full-fledged multi-country dynamic stochastic general equilibrium model of the EMU, which is beyond the scope of the paper. A much simpler method to illustrate the uncertainty related to measuring stress in country j , is to view it as a random variable and to calculate confidence intervals using

the sampling distribution of the estimators of the ECB Taylor rule:

$$\begin{aligned}
\mathbf{S}_{j,t} &= [\bar{\pi}_{EA,t} - \bar{\pi}_{j,t}] + \\
&+ [\boldsymbol{\alpha}_{EA}\Delta\bar{y}_{EA,t} - \boldsymbol{\alpha}_j\Delta\bar{y}_{j,t}] + \\
&+ [\boldsymbol{\beta}_{EA}(E_t\pi_{EA,t+k} - \bar{\pi}_{EA,t}) - \boldsymbol{\beta}_j(E_t\pi_{j,t+k} - \bar{\pi}_{j,t})] + \\
&+ [\boldsymbol{\gamma}_{EA}(E_t\Delta y_{EA,t+k} - \Delta\bar{y}_{EA,t}) - \boldsymbol{\gamma}_j(E_t\Delta y_{j,t+k} - \Delta\bar{y}_{j,t})]. \quad (6)
\end{aligned}$$

In Equation (6) random variables are highlighted in bold. $\boldsymbol{\alpha}_j$, $\boldsymbol{\beta}_j$ and $\boldsymbol{\gamma}_j$ have the same sampling distribution as the estimators for α_{EA} , β_{EA} and γ_{EA} , respectively. In the bootstrap they are, however, independently drawn from each other implying that country-specific reaction coefficients may deviate from the estimated ECB reaction coefficients, albeit only in a non-systematic way. It is clear that the resulting confidence intervals do not truly reflect the two biases described above, as they only account for the uncertainty resulting from the estimation of the ECB reaction coefficients. Notwithstanding this caveat, we use the upper (lower) confidence region to illustrate the credibility (stability) bias.

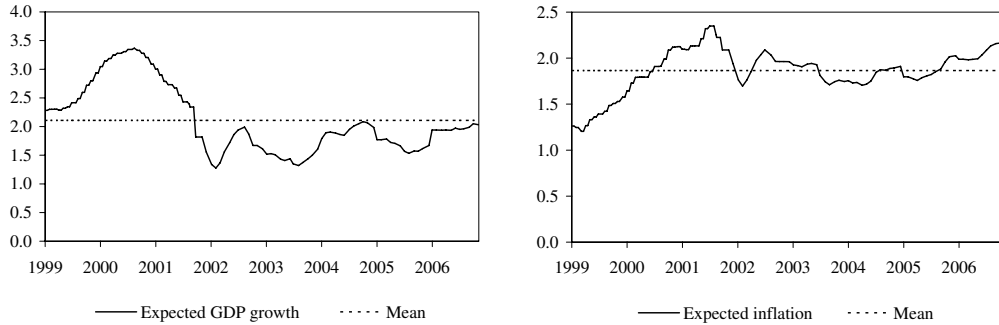

3 Data

To capture the forward-looking aspect of monetary policy, we take the expected growth and inflation rates from consensus forecasts as published on a monthly basis by Consensus Economics Inc.³ Every month, Consensus Economics Inc. surveys a large number of prominent financial and economic forecasters for their estimates of a range of variables including future growth, inflation, interest rates and exchange rates. Most industrialized countries in the world are covered and reference data are quickly disseminated. Forecasts are made for the current and the following year. The number of panelists ranges from 10 to 30 for each of the countries, and for the European countries the panelists are generally based in countries they forecast.

To our knowledge, only a handful of studies have used the consensus forecasts of Consensus Economics Inc. Among these studies Harvey et al. (2001), Loungani (2001) and Isiklar et al. (2006) contain formal tests of forecast efficiency. Although most studies agree that there are some inefficiencies in the forecasts, it nevertheless appears difficult for individual institutes to outbeat the consensus forecast over prolonged periods of time.

³As Consensus Economics Inc. does not publish inflation and growth forecasts for Luxembourg, we are not able to include this country in our analysis. Given its GDP share of approximately 0.3 percent of euro area GDP, this will hardly affect the results. In a similar vein, it is not possible to carry out the analysis for the new EU member countries as data on GDP growth and inflation expectations back to 1999 are not available.

Figure 1: 12-months ahead consensus forecasts of GDP growth and inflation for the euro area

Source: Consensus Economics Inc.

Only in December 2002, Consensus Economics Inc. started publishing forecasts for the euro area. Hence, for our analysis—which starts at the introduction of the euro in 1999—we are forced to aggregate the country-specific survey results using GDP weights to the euro area. To be consistent we use this strategy for the entire sample period. As we will use the country-level data to construct country-specific stress indicators, this also ensures consistency in this respect. The correlation coefficient between our constructed euro area aggregates and the reported consensus results (for the sample since December 2002) are 0.93 and 0.98 for, respectively inflation and GDP growth.

To implement our theoretical framework presented in the previous Section, we need to make a number of assumptions. First, we will use the consensus forecasts (i.e. averages of the individual responses) of annual average real GDP growth and inflation for the upcoming 12 months, i.e. in the empirical analysis we will set $k = 12$. Second, we assume the target inflation rates to be constant and proxy them by the expected inflation averages over the sample, i.e. $\bar{\pi}_{j,t} = \bar{\pi}_j = 1/T \sum_{t=t_0}^T E_t \pi_{j,t+k}$. Finally, trend growth is also approximated by its expected average over the sample: $\Delta \bar{y}_{j,t} = \Delta \bar{y}_j = 1/T \sum_{t=t_0}^T E_t \Delta y_{j,t+k}$.⁴ Hence, we make the simplifying assumption that the trend growth rate is constant. While this is clearly at odds with the theoretical concepts developed inter alia by Woodford (2003), it might nevertheless be a good approximation for the relatively short time

⁴Alternatively, it would be possible to assume that either the neutral real interest rate or the inflation target is the same across all European countries. While the estimated ECB policy rule would not be affected by this, the cyclical stress measures would have a non-zero mean over the sample period and the interpretation of the two stress components would change. Overall stress would only be marginally affected.

period we consider and avoids the use of filter techniques, which are difficult to apply on the relatively short sample defined by the operation period of the ECB.⁵ Figure 1 shows both time series for the euro area.⁶

We use data at the frequency of the ECB Governing Council meetings since 1999 and until the end of 2006 throughout the paper. There are some differences in the number of ECB Governing Council meetings during the years. Whereas in the 1999–2001 period there were two meetings each month, the Council only met once a month from 2002 on. As described by De Haan et al. (2005), the ECB has a range of instruments at its disposal for implementing monetary policy. To manage liquidity in the money market and steer short-term interest rates, it uses open market operations. The main refinancing operations are considered to be the most important and are executed as standard weekly tenders for liquidity-providing reverse transactions with a two-week maturity. We use the associated main refinancing rate as set at the Governing Council meetings as our proxy for monetary policy.⁷

4 Empirical results

4.1 Taylor rule estimation

In this Section we determine the reaction coefficients α_{EA} , β_{EA} and γ_{EA} , which are required to compute country-specific stress, by estimating the nested Taylor rule model that consists of Equations (1), (2) and (3). The estimation results are summarized in Table 1. In accordance with most empirical studies on Taylor rules, the smoothing parameter ρ_{EA} is positive and highly significant. Our estimates imply that each month the ECB only closes about 10 percent of the gap between the actual main refinancing rate and the desired interest rate level. However, we do not find any evidence of a positive serial correlation in the error term, which contrasts with the results obtained by Gorter et al. (2007). In fact our estimate for δ_{EA} is negative, which can be explained by the time series characteristics of our dependent variable.⁸ For this reason and as the inclusion of serially correlated errors

⁵See for example Garnier and Wilhelmsen (2005) for the estimation of an unobserved components model with the Kalman filter using artificial euro area data from 1963 to 2004.

⁶Appendix B shows the country-specific time series.

⁷Note that the main refinancing rate usually moves synchronised with the two rates associated to the two standing facilities, the marginal lending or Lombard facility and the deposit facility. The standing facilities constitute a corridor for the (inter-bank) money market rate.

⁸While the main refinancing rate only exhibits 21 discrete changes over the sample period and is constant over the rest of the period, the changes in the three-month interbank

| | OLS | | IV |
|---|-------------------|------------------|------------------|
| Interest rate smoothing (ρ_{EA}) | 0.91** (0.02) | 0.90** (0.03) | 0.90** (0.03) |
| Neutral real rate (α_{EA}) | 0.50** (0.06) | 0.50** (0.06) | 0.50** (0.06) |
| Inflation expectations (β_{EA}) | 1.63** (0.44) | 1.63** (0.43) | 1.65** (0.42) |
| Expected output growth (γ_{EA}) | 1.56** (0.18) | 1.52** (0.17) | 1.51** (0.17) |
| Serially correlated error (δ_{EA}) | -0.14** (0.04) | – | – |
| Cragg-Donald statistic | – | – | 1070.3 |
| Hausman p-value | – | – | 0.9983 |
| Quandt-Andrews p-value | – | 0.2984 | – |

Notes: Heteroscedasticity and autocorrelation consistent standard errors shown in parentheses. * denotes significance at 10%, and ** significance at 5%. The instruments of the IV regression are: $i_{EA,t-2}$, $E_{t-1}\pi_{EA,(t-1)+12}$, $E_{t-2}\pi_{EA,(t-2)+12}$, $E_{t-1}\Delta y_{EA,(t-1)+12}$, $E_{t-2}\Delta y_{EA,(t-2)+12}$. The critical value of the Cragg-Donald statistic is a function of the number of potentially endogenous regressors (n), the number of instruments (K_2) and the desired maximal bias of the IV estimator relative to OLS (b). For a significance level of 5%, $n = 2$, $K_2 = 5$ and $b = 0.05$ the critical value is 13.97.

Table 1: Estimation results for the euro area Taylor rule, 1999–2006

has no significant impact on the estimates of the remaining parameters, we decided for the Taylor rule model without serial correlation (i.e. the second column in Table 1) as our benchmark specification.

The reaction coefficients α_{EA} , β_{EA} and γ_{EA} are all statistically significant and show the expected positive signs. The estimate for α_{EA} suggests that the neutral real interest rate is equal to one half of the trend growth rate of real GDP. Given a mean of expected GDP growth over the sample period of 2.1 percent and a mean of expected inflation of 1.9 percent (see Figure 1), the estimated nominal and real neutral rates are about 3 percent and 1.1 percent, respectively. While the value for the nominal neutral rate simply reflects the average nominal refinancing rate over the 1999-2006 period, it is much lower than the estimates obtained in studies using a longer sample. Garnier and Wilhelmsen (2005) who also assume a linear relationship between the neutral real rate and the trend growth rate of GDP, report an estimate for α_{EA} of

rate, which is used by Gorter et al. (2007) as dependent variable, are more continuous. Below in Table 2 we will confirm the results by Gorter et al. (2007) and show that a positive serial correlation in the error term can be obtained by using the Euribor three-month interbank rate as dependent variable.

around 0.9, which implies a neutral real and nominal rate of 3.8 percent and 1.9 percent, respectively.

The coefficient β_{EA} measures the response of the ECB to changes in inflation expectations. If inflation expectations rise by 1 percentage point, the ECB will raise its target rate by 1.63 percentage points. Thus, the interest rate policy of the ECB is stabilizing as it clearly fulfills the Taylor principle, which says that real interest rates should increase following a rise in (expected) inflation. Studies like Gerdesmeier and Roffia (2004), Surico (2003), as well as Ullrich (2003), which use realised inflation and output data, estimated small reactions to inflation movements and thereby have suggested a destabilising role of the ECB. As noted by Sauer and Sturm (2003, 2007) and more recently by Castelnuovo (2007) and Gorter et al. (2007), this can largely be attributed to the use of backward-looking as compared to forward-looking specifications.⁹ Hence, more recent papers focusing on the euro area, like Fendel and Frenkel (2005, 2006) and Hayo and Hofmann (2006), specify Taylor rules in a forward-looking manner. These more recent studies report coefficient estimates for β_{EA} between 1.5 and 2.0.

The positive and highly significant coefficient of the expected output gap γ_{EA} implies that above average growth indeed leads to higher interest rates. This is perfectly in line with previous literature. Our coefficient estimates suggest that the ECB takes movements in real variables at least as serious as movements in inflation.

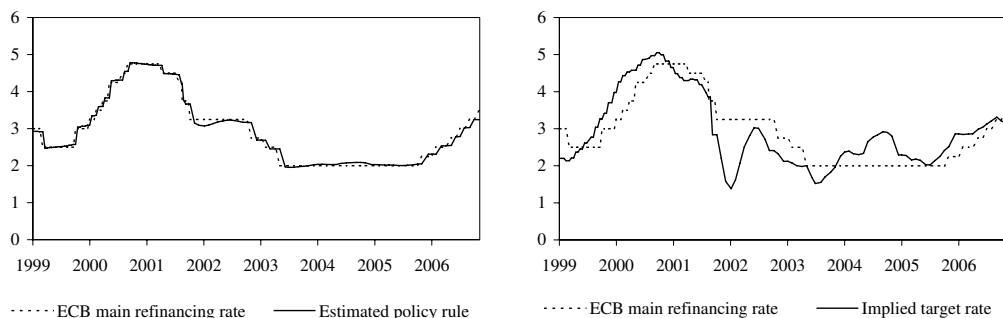

In addition to the coefficient estimates, Table 1 reports the p-value of the Quandt-Andrews structural change test. As the null hypothesis that there are no breakpoints within trimmed data cannot be rejected at conventional levels, the OLS regression is unlikely to suffer from instability.¹⁰

Another potential problem, which arises when expectations for inflation and GDP growth are made under the assumption that the policy rate will not be constant within the forecasting horizon, is that the OLS regression

⁹As compared to the US, where Orphanides (2001) has shown that estimated policy reaction functions obtained using the ex-post revised data can yield misleading descriptions of historical policy, the use of real-time data appears to be of minor influence. Nevertheless, by using consensus forecasts also this real-time aspect is directly dealt with in this paper.

¹⁰The Quandt-Andrews breakpoint test tests for one, or more, unknown structural breakpoints in an equation's sample. The basic idea behind the Quandt-Andrews test is that a single Chow breakpoint test is performed at every observation between two dates τ_1 and τ_2 . The k test statistics from those Chow tests are then summarized into one test statistic for a test against the null hypothesis of no breakpoints between τ_1 and τ_2 . As the distribution of the statistics becomes degenerate as τ_1 approaches the beginning of the equation sample, or τ_2 approaches the end of the equation sample, it is typical to exclude the first and the last 7.5 percent of the observations, leading to 15 percent trimming of the sample.

Figure 2: Taylor rule estimation

may be subject to endogeneity of the regressors.¹¹ This would cause the estimates to be inconsistent. To test for the exogeneity of our right-hand-side variables, we run a Hausman test. The final column of Table 1 shows the IV estimators of a 2SLS regression. As instruments for expectations we use the first and the second lag of the explanatory variables.¹² The Hausman test compares the estimated coefficients of the IV and OLS regressions in the last two columns of Table 1. The null hypothesis that the OLS estimator yields consistent and efficient estimates cannot be rejected at conventional levels. Hence, we can safely conclude that endogeneity of neither inflation nor growth expectations is empirically an issue.

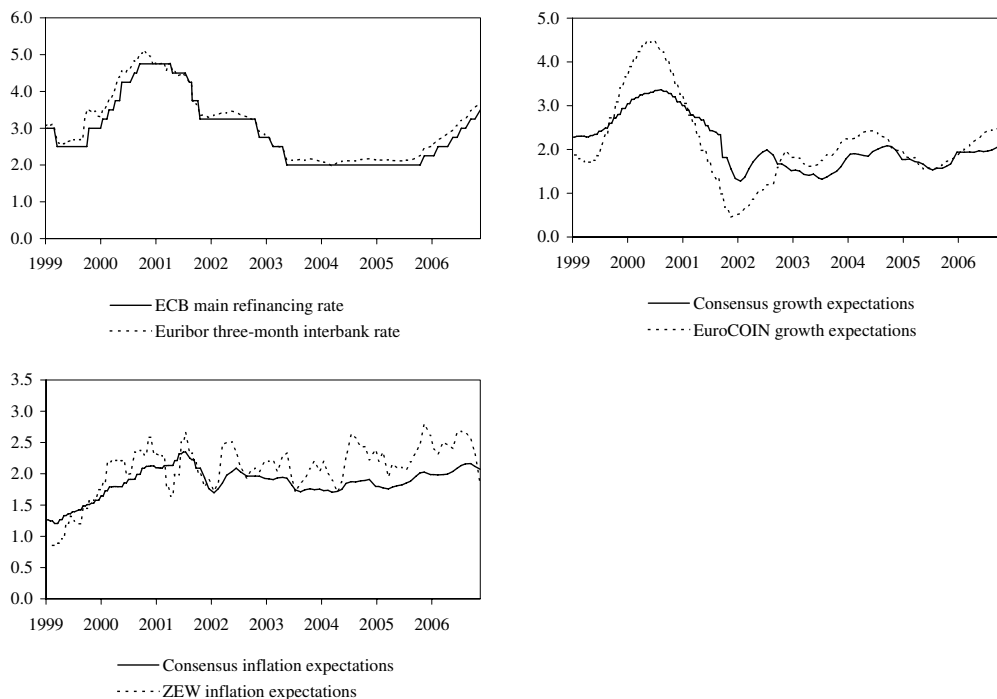

The fit of our baseline specification is illustrated in Figure 2. It shows the modified Taylor rule rate with and without interest smoothing. Except for the winter of 2001/2002, in which both growth and inflation expectations plummeted but the ECB did not further lower its interest rates, the estimated modified Taylor rule appears to lead actual ECB interest rate decisions quite well. If the Taylor rate lies above the ECB main refinancing rate, then an interest rate increase is more likely to happen than a decrease. The reverse holds for Taylor rates below the actual ECB interest rate.

To further check the robustness of our baseline forward-looking Taylor rule specifications, we experiment with alternative expectation and policy rate measures. First, we replace the main refinancing rate as a proxy for the

¹¹Note, though, that as we know when each observations of each of time series has been published, we are certain that all information listed on the right-hand side of our nested equation is publicly available before each interest rate decisions is actually made.

¹²Table 1 reports the Cragg and Donald (1993) statistic, which is the smallest eigenvalue of the matrix analog of the F-statistic from the first-stage regression. The null hypothesis that the instruments are weak is rejected if the Cragg-Donald statistic exceeds the critical value. The critical values are presented by Stock and Yogo (2005). The test strongly rejects the null hypothesis of weak instruments.

policy rate by the ECB's operating target, the Euribor three-month interbank rate. Then we take as an alternative source for GDP growth expectations the EuroCOIN indicator. This indicator is published by the Centre for Economic Policy Research (CEPR) and provides an estimate of the monthly growth rate of euro area GDP. Finally, with respect to inflation, the Germany-based Centre for European Economic Research (ZEW) queries 6-months-ahead euro area inflation expectations among German financial markets experts. As the ZEW data is qualitative, it is converted into quantitative measures of inflation expectations using the probability approach pioneered by Carlson and Parkin (1975) and adapted for the ZEW data by Heinemann and Ullrich (2006).¹³ As shown by Figure 3 especially the alternative expectation measures do vary across the different data sources.

Table 2 shows the Taylor rule coefficients when these alternative data sources are used one at a time. The main results can be summarized as follows. Interest rate smoothing is an important and significant element of the ECB's monetary policy strategy, irrespective of the data used for proxying

¹³Appendix A briefly explains the procedure of Heinemann and Ullrich (2006).

| | Euribor | | EuroCOIN | ZEW |
|---|------------------|------------------|------------------|------------------|
| Interest rate smoothing (ρ_{EA}) | 0.92** (0.03) | 0.91** (0.03) | 0.96** (0.01) | 0.93** (0.02) |
| Neutral real rate (α_{EA}) | 0.58** (0.08) | 0.58** (0.08) | 0.52** (0.13) | 0.40** (0.08) |
| Inflation expectations (β_{EA}) | 1.17* (0.66) | 1.17* (0.67) | 1.69** (0.84) | 1.09** (0.33) |
| Expected output growth (γ_{EA}) | 1.58** (0.23) | 1.50** (0.23) | 1.36** (0.34) | 1.77** (0.23) |
| Serially correlated error (δ_{EA}) | — | 0.23** (0.08) | — | — |

Notes: Heteroscedasticity and autocorrelation consistent standard errors shown in parentheses. * denotes significance at 10%, and ** significance at 5%.

Table 2: Robustness of the Taylor rule estimation

inflation and growth expectations. When we use the Euribor three-month interbank rate as dependent variable, the serial correlation model is confirmed, without having any significant impact on the remaining reaction coefficients. The various estimates for α_{EA} , β_{EA} and γ_{EA} show that our baseline estimates represent a good “mean” of the ECB’s reaction coefficients. In all three cases, the Taylor principle is fulfilled. Moreover, the 95% confidence bands of the point estimates in Table 2 overlap with those of our preferred forward-looking Taylor rule specifications in Table 1. Thus, we conclude that our baseline estimates are very robust against the use of alternative proxies for expectations and the policy rate.

4.2 The counterfactual scenario

Before we proceed to the calculation of stress for the individual member countries and the euro area as a whole, we present some empirical support for the assumption of our counterfactual scenario that the national central banks would implement a similar policy rule as the ECB—if they had the choice to do so. For this purpose we estimate Taylor rules for countries, which are not part of the EMU and whose monetary policy strategy is akin to that of the ECB. We decided for four (Western) European countries (Denmark, Sweden, Switzerland and the UK), in which in the past there has already been a debate about EMU accession.

For the estimation of the Taylor rules we use the most general model specification with Consensus expectations and a lagged dependent variable as explanatory variables and a serially correlated error. The dependent variable is the monthly average of the three-month interbank rate. As for the ECB

| | Denmark | Sweden | Switzerland | UK |
|--|------------------|------------------|------------------|------------------|
| Interest rate smoothing (ρ_j) | 0.93** (0.03) | 0.93** (0.02) | 0.89** (0.03) | 0.96** (0.02) |
| Neutral real rate (α_j) | 0.63** (0.17) | 0.56** (0.11) | 0.28** (0.11) | 1.01** (0.22) |
| Inflation expectations (β_j) | 3.99** (1.48) | 1.89** (0.59) | 1.64** (0.66) | 2.31 (3.54) |
| Expected output growth (γ_j) | 2.77* (1.68) | 1.48** (0.70) | 1.56** (0.51) | 2.64 (1.67) |
| Serially correlated error (δ_j) | 0.28 (0.20) | 0.40** (0.13) | 0.21 (0.14) | 0.35** (0.18) |

Notes: Heteroscedasticity and autocorrelation consistent standard errors shown in parentheses. * denotes significance at 10%, and ** significance at 5%.

Table 3: Estimation results for the Taylor rule in non-EMU countries, 1999–2006

Taylor rule the sample period goes from 1999 to 2006.

The results, which are summarised in Table 3, show that—except for the UK—the modified Taylor rule specification is a good description of recent monetary policy in these countries. The central banks react positively to expected deviations of inflation and output growth from target rates, interest rate smoothing plays an important role, the neutral real interest rates are pinned down by trend growth rates, and serial correlation in the error term is significant for Sweden and the UK. Most importantly, however, the results seem to confirm the credibility bias that has been elaborated in Section 2.3: the estimates of the reaction coefficients β_j and γ_j are generally larger than those obtained in the baseline estimation of the ECB policy rule.

In addition to that, the four non-EMU countries also provide some evidence for the stability bias. Table 4 shows that both, the variance of inflation expectations and the variance of expected output growth, are generally smaller than the average variances over all EMU countries. Thus, country-specific monetary policy seems to stabilise expectations more than area-wide policy.

4.3 Stress from a country perspective

For the calculation of country-specific stress we use the point estimates of the Taylor rule parameters α_{EA} , β_{EA} and γ_{EA} of the baseline regression (second column in Table 1) together with the country-specific consensus forecasts. Then using Equation (6) allows us to create Figure 4. The solid lines represent the case where country-specific reaction coefficients and ECB reaction

| | $Var[E_t\pi_{j,t+12}]$ | $Var[E_t\Delta y_{j,t+12}]$ |
|----------------------------|------------------------|-----------------------------|
| Denmark | 0.27 | 0.27 |
| Sweden | 0.52 | 0.64 |
| Switzerland | 0.31 | 0.46 |
| UK | 0.17 | 0.49 |
| average over EMU countries | 0.38 | 0.68 |

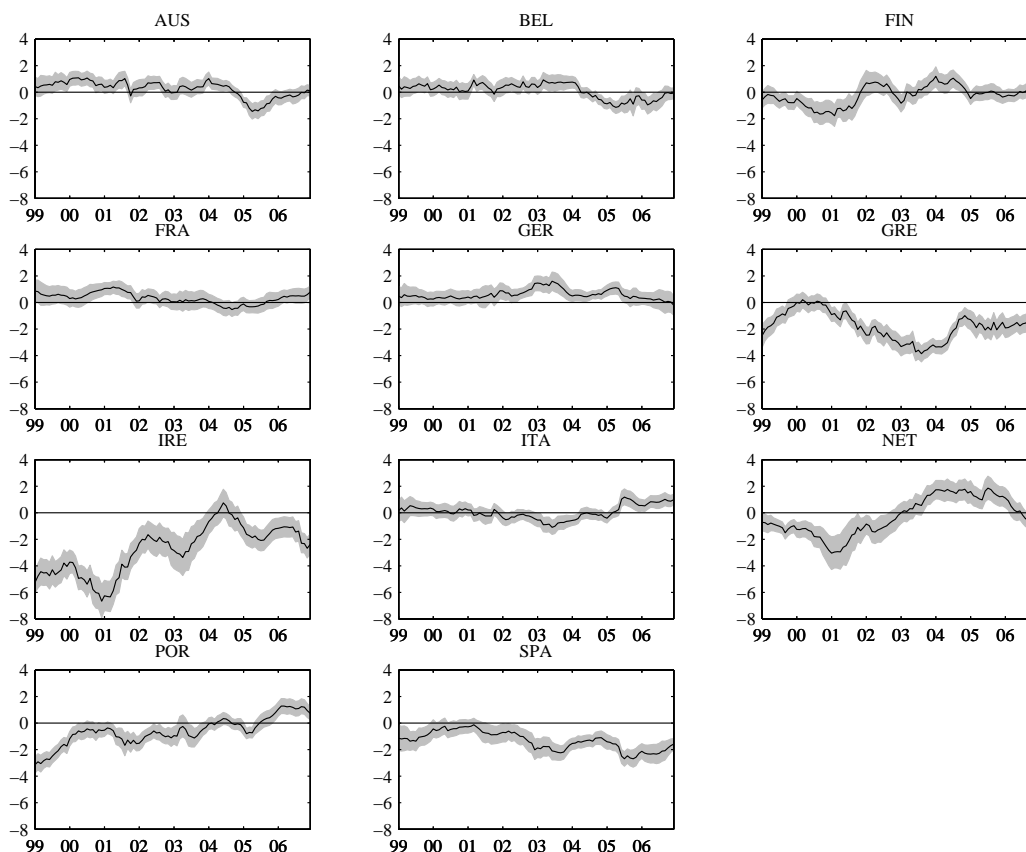

Table 4: Variance of inflation and output growth expectations, 1999–2006

coefficients are identical. The confidence intervals are calculated as the 0.025 and 0.975 quantiles of the sampling distribution obtained from a bootstrap procedure with 1,000 replications. In each replication of the bootstrap procedure the reaction coefficients are independently drawn from the sampling distribution, so that α_j , β_j and γ_j may deviate randomly from α_{EA} , β_{EA} and γ_{EA} , respectively.

The figure highlights that in countries like Greece, Ireland, Portugal and Spain, stress has been negative for most of the EMU period. This implies that if, for example, the ECB had conducted monetary policy for Ireland alone, it would have set nominal interest rates almost 7 percentage points higher at the end of 2000. At the other extreme end is Germany, where stress has always been positive. There, the interest rate would for instance have been 1.6 percentage points lower in mid-2003. Overall the actual monetary policy of the ECB seems to have been relatively appropriate for countries like Belgium and Italy. In those countries the average stress levels were close to zero and only showed moderate fluctuations. Also in the Netherlands and Finland average stress levels were close to zero. Here, however, clearly more pronounced cyclical patterns are visible. Stress levels in the Netherlands, for instance, ranged from -3 percent to 1.9 percent.

Figures 5 to 7 show the decomposition of country-specific stress related to differences in inflation and growth expectations into its cyclical and structural components (see Equation (5) for details on the decomposition). As by construction average cyclical stress in each country is zero, the sum of both components of structural stress accounts for the average overall stress. Especially Greece, Ireland, Portugal and Spain have experienced negative structural stress levels. As shown by Figure 5, this is to a large part explained by relative high average inflation expectations in those countries. Only for Ireland above average growth expectations played a more important role. In most of the remaining countries structural stress related to differences in growth and inflation expectations either was close to zero or compensated each other so that overall structural stress was close to zero.

Figure 4: Country-specific stress

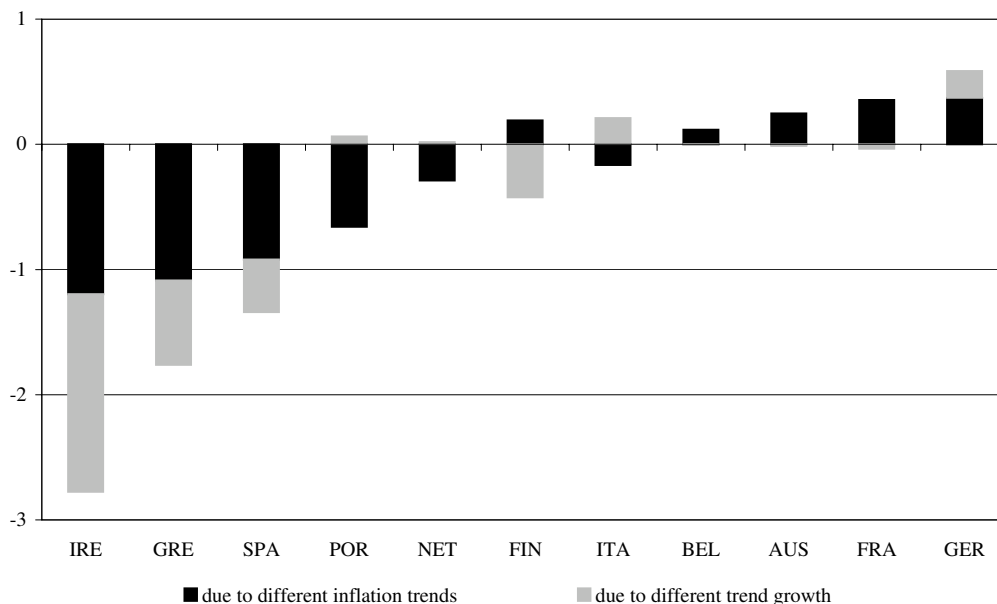

Notes: The shaded areas are 95 percent confidence intervals, which are calculated as the 0.025 and 0.975 quantiles of the sampling distribution obtained from a bootstrap procedure with 1,000 replications.

A notable exception is Germany where structural stress was highest due to both, low average inflation expectations and low average growth expectations. Put into numbers, if the ECB had conducted monetary policy for Germany alone, the neutral nominal interest rate, and hence the average interest rate over the 1999-2006 period, would have been 0.6 percentage points below its actual level.

Ireland not only had the highest (absolute) level of structural stress, but also its cyclical stress was more pronounced than in other countries. This is explained by both a more pronounced growth and inflation cycle in Ireland than elsewhere and a different timing of the cycle (see Figures 6 and 7). Also in the Netherlands cyclical fluctuations in inflation were, on average, rather strong during the past eight years, with inflation expectations above 3.5 per-

Figure 5: Structural stress

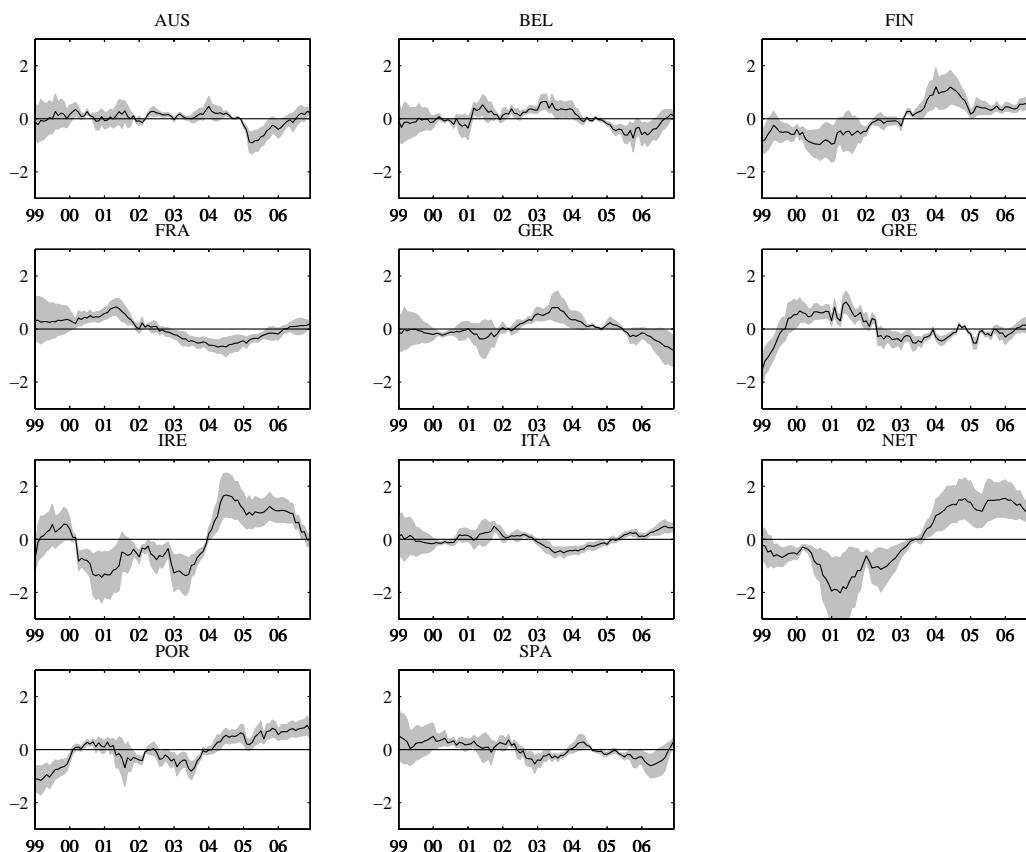

cent during the first half of 2006 and expectations as low as 1.25 percent in 2005. These cyclical misalignments in inflation expectations alone would have warranted a 2.0 percentage point higher main refinancing rate for the Netherlands in the second quarter of 2001 and a 1.5 percentage point lower one at the beginning of 2005. Cyclical stress in Germany, on the other hand, has been relatively low overall. Only the year 2003, in which inflation expectations in Germany fell significantly, stands out in this cyclical perspective; combined also with cyclically low growth, the main refinancing rate should have been almost 1.0 percentage points lower from a purely German perspective in the third quarter of 2003. Combined with the above-mentioned structural stress, this would imply a main refinancing rate of only 0.4 percent instead of the actual rate of 2.0 percent.

4.4 Stress from a European perspective

By aggregating the stress indicators to a euro area level and analysing their developments over time, our framework allows to construct useful measures of synchronisation tendencies within the euro area. For this purpose we first have to find an appropriate weighting scheme. From a positive point of view, the primary objective of the ECB is price stability. This has been defined by its Governing Council to imply a year-on-year increase of the Harmonised

Figure 6: Stress due to asynchronous inflation cycles

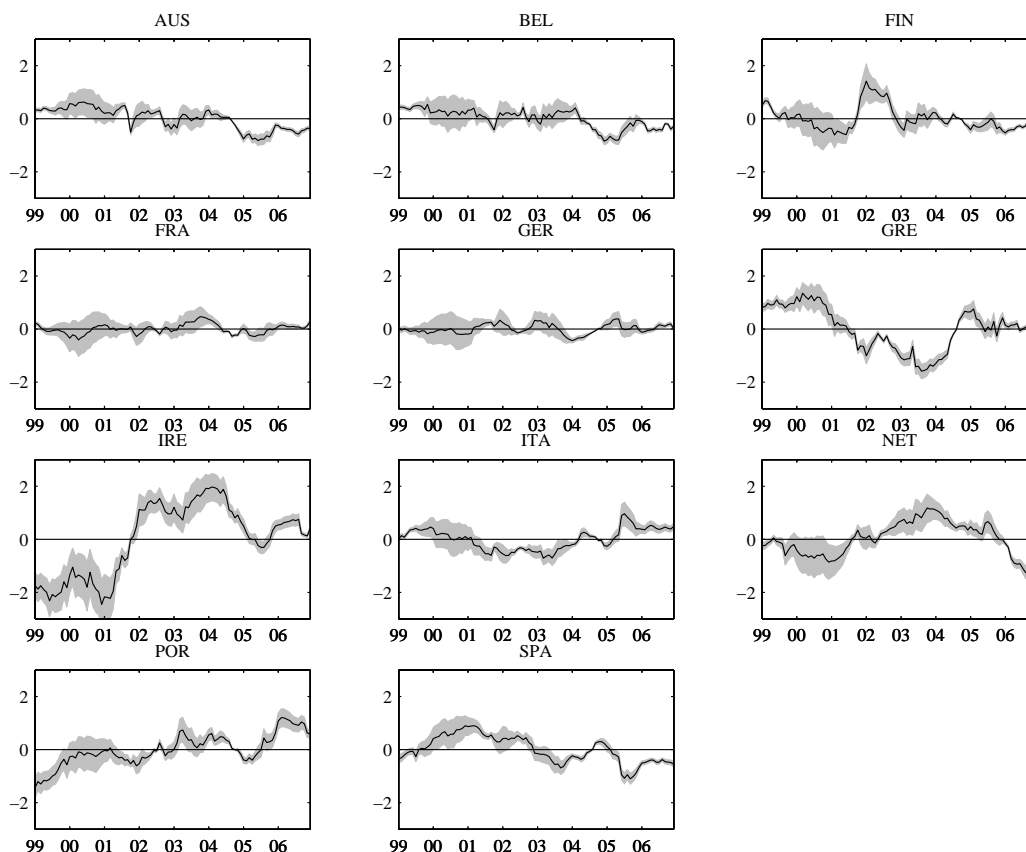

Notes: The shaded areas are 95 percent confidence intervals, which are calculated as the 0.025 and 0.975 quantiles of the sampling distribution obtained from a bootstrap procedure with 1,000 replications.

Index of Consumer Prices (HICP) for the euro area, which does not exceed 2 percent in the medium term. The euro area HICP is a GDP-weighted average of the country-specific harmonised consumer price indices.¹⁴ Hence, if we assume that decision making in the ECB Governing Council always results in policy decisions which maximise the welfare of the whole monetary union, i.e. the members of the council take a truly euro area perspective, we

¹⁴To be precise, the country weights calculated by Eurostat are derived from national accounts data for household final monetary consumption expenditure. A comparison between the average Eurostat weights and the average GDP shares over the 1999-2006 period shows that discrepancies between the two weights are very small.

Figure 7: Stress due to asynchronous growth cycles

Notes: The shaded areas are 95 percent confidence intervals, which are calculated as the 0.025 and 0.975 quantiles of the sampling distribution obtained from a bootstrap procedure with 1,000 replications.

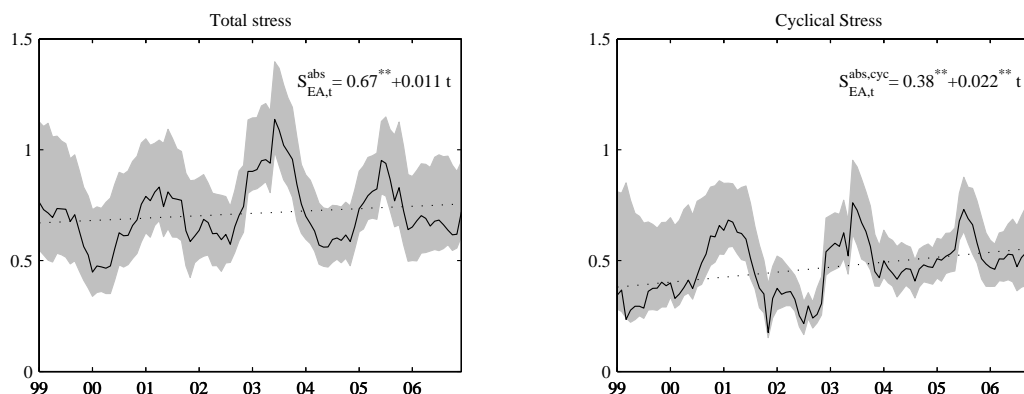

should use GDP shares to weigh the individual country stress levels as well.¹⁵ To be able to aggregate stress indicators to the euro area, we furthermore neglect the sign of the stress level at a country level.¹⁶ Hence, we make the simplifying assumption that too high and too low interest rates are causing stress to an equal degree. Hence, we compute aggregate stress in the euro area as a GDP weighted average of absolute country-specific stress levels: $S_{EA,t}^{abs} = \sum_j w_j |S_{j,t}|$, where w_j is the weight attributed to country j .

On average, aggregate absolute stress equals 0.71 percentage points. Stress levels are, however, not constant over time. Figure 8 shows how overall stress

¹⁵The use of GDP shares is also consistent with the way we constructed area-wide aggregates of the national expectation series.

¹⁶By construction, euro area stress would otherwise always equal zero.

Figure 8: Weighted absolute sum of stress in the euro area

Notes: The shaded area are the 95 percent confidence interval, which are calculated as the 0.025 and 0.975 quantile of the sampling distribution obtained from a bootstrap procedure with 1,000 replications. As the distribution of country-specific absolute stress is truncated at zero and hence skewed to the right, the confidence intervals around the means (which are computed using the point estimates of the baseline Taylor rule regression) are asymmetric. The dotted lines are linear trends of the means, whose estimated intercepts and (annualised) slopes are indicated in each graph. * denotes significance at 10%, and ** significance at 5%.

has evolved. In particular, during 2003 and in the summer of 2005 stress levels were relatively high in the euro area, indicating large business cycle asymmetries across euro area countries. On the other hand, there are periods where stress levels clearly fell, indicating that a common shock hit the euro area. For instance, the common shock due to September 11, 2001 allowed the ECB to reduce stress in all member countries at the same time.

Figure 8 also shows that overall euro area stress does not show a downward trend over time; if anything there is a slight—but insignificant—upward trend. Focusing on cyclical stress only ($S_{EA,t}^{abs,cyc} = \sum_j w_j |S_{j,t}^{cyc}|$), the positive trend even becomes significant. For a correct interpretation, it must be emphasised that trends in total stress are exclusively determined by cyclical stress, whereas structural stress only contributes to the average level of total stress. Hence, this result does not suggest that the degree of business cycle synchronisation has steadily increased during the past eight years. This speaks against the argument that the introduction of a monetary union automatically reduces differences in cyclical developments among its member countries.

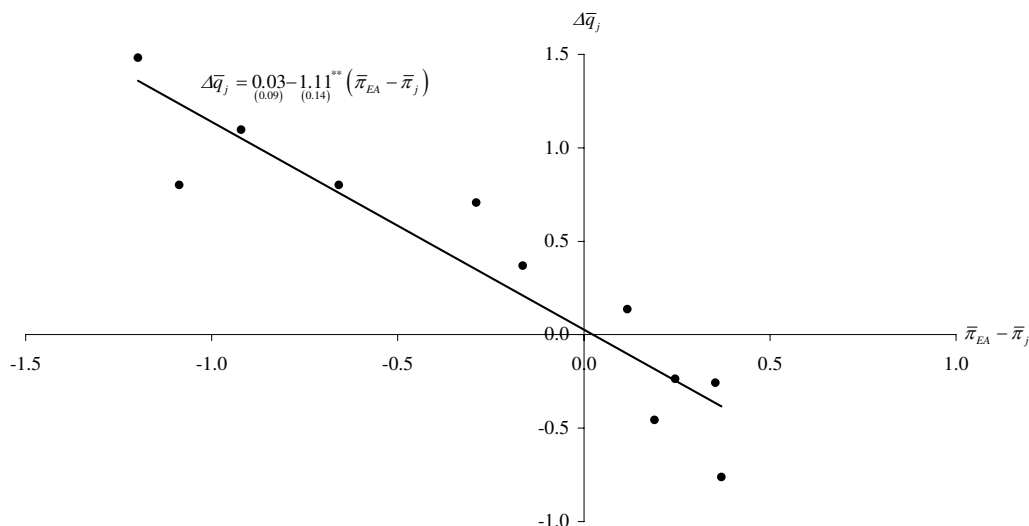

4.5 Discussion of the results

4.5.1 Structural stress and the real exchange rate channel

At least on a euro area level, stress is quite persistent over our eight year sample. The finding that stress is not decreasing over time in the euro area as a whole is, in many eyes, a very unsatisfactory result. In particular the fact that in most of the euro area countries interest rates are systematically too low or too high over such a long period of time must raise the question whether stress is not reinforcing itself. By focussing on the interest rate alone when calculating monetary stress, we so far ignored an important adjustment mechanism that operates within a monetary union. According to the real exchange rate channel, inflation differentials between countries in the monetary union lead to changes in the relative price competitiveness among these countries, and hence to changes of the real exchange rate of euro area member countries relative to their euro area trading partners. When, for example, in countries with high structural inflation (which for most countries in our sample goes along with a higher trend growth rate of GDP relative to the EMU average) ECB policy rates are too expansive on average (i.e. stress is negative), an appreciating real exchange rate may, to a certain degree, compensate for this. An important feature of the real exchange rate channel are its accumulative dynamics. The longer structural inflation differentials persist, the more the relative price competitiveness improves or deteriorates and the more the real exchange rate channel compensates (or even overcompensates) the interest rate channel (irrespective of the elasticities of GDP and inflation with respect to the interest rate and the exchange rate).

To avoid the problems related to the estimation of open economy Taylor rules (see e.g. Fourçans and Vranceanu, 2004, and Carstensen and Colavecchio, 2006 for attempts to take into account exchange rate movements in an ECB Taylor rule), we address the exchange rate issue in a rather qualitative fashion. Figure 9 depicts the average real appreciation of a country vis-à-vis the rest of the euro area (measured as the average annualized change of the real exchange rate over the previous month in percent) against the structural inflation stress (in percentage points). The scatter plot, in which the dots all lie very close to a falling 45°-line, suggests that structural inflation stress is compensated almost one-to-one by a change in the real exchange rate. If, for example, inflation in one country was on average over the 1999-2006 one percentage point higher than in the euro area as a whole (implying a negative stress in this country), the real exchange rate appreciates by about one percent per annum. This appreciation of the currency vis-à-vis the rest of the euro area counteracts the on average expansive monetary policy stance

Figure 9: The compensating role of the real exchange rate

Notes: $\Delta \bar{q}_j$: average annualized change of the real exchange rate of country j vis-à-vis the rest of the euro area over the previous month in percent (increase indicates real appreciation); $\bar{\pi}_{EA} - \bar{\pi}_j$: difference between the average expected inflation in the euro area and the average expected inflation in country j in percentage points (structural inflation stress). Heteroscedasticity and autocorrelation consistent standard errors shown in parentheses. * denotes significance at 10%, and ** significance at 5%.

due to the on average higher inflation rate.

In addition, the direct effect of the change in the real exchange rate is complemented by a drift of the real exchange rate away from its initial level, which is increasing in time. For the country in the above example this implies that, after eight years, the level of the real exchange rate is (roughly) 8% higher than at the beginning of EMU. The extent to which this appreciation of the real exchange rate has a contractionary impact on the country crucially depends on the level of the equilibrium real exchange rate. If the real exchange rate was at its equilibrium at the beginning of EMU, the increase of the real exchange rate was indeed compensating for the negative monetary stress. If, by contrast, the exchange rate of the country was undervalued by, say, 8% in real terms at the beginning of EMU, the increase in the real exchange rate only implies a reduction of the stimulating relative price advantages.

Due to this time dependency of the change in the relative price competitiveness, the impact of the real exchange rate channel on total stress would increase over time, irrespective of the response coefficient in an augmented

Taylor rule. As a general rule, the longer structural inflation differences persist, the more the related drift of the level of the real exchange rate would compensate for this type of structural stress.

4.5.2 Cyclical stress and the weighting of member countries in the monetary policy decision process

Not only the result that (cyclical) stress at the euro area level is increasing rather than decreasing over time, but also the contribution of each member country to total stress requires some further discussion. In this Section we assume that the ECB takes structural differences across member countries as given and has a focus on stabilising cyclical movements.¹⁷ So far, we have modeled a decision process within the ECB in which the decision makers act fully in the interest of the euro area as a whole and have therefore used GDP shares for the aggregation of national to area-wide data. The country decomposition of absolute cyclical stress in Table 5 shows that in the case of GDP weights the cyclical component of aggregate euro area stress has been very unevenly distributed across EMU member countries. Especially the large countries, and in particular Germany, have much higher weighted absolute cyclical stress levels and therefore implicitly have received a lower political weight than suggested by their economic share in euro area GDP. Hence, this analysis suggests that GDP weights seem not to reflect the actual representation of countries within the monetary policy decision process of the ECB.

The representation of regional interests within a federal central bank like the ECB has received much attention in recent years. One strand of the literature addresses the question whether there is any empirical evidence of regional voting behaviour within a federal central bank. Berger and De Haan (2002) show that within the Bundesbank's Governing Council the probability of a regional representative to vote against the majority vote increased in the difference between their respective regional and national economic developments, in particular inflation and real GDP growth. Similar indications for the actual ECB policy and the US Federal Open Market Committee are provided by Heinemann and Hüfner (2004) and Meade and Sheets (2005), respectively. Another strand of the literature investigates whether misrepre-

¹⁷This assumption is also in accordance with the ECB's official statements: "We all know that the very existence of a single monetary policy and thereby a uniform policy interest rate across the euro area countries does not allow using monetary policy to influence output growth differentials across euro area countries.(...) Addressing 'unsatisfactory' output growth performances in individual countries must be tackled by properly designed national policies in the fiscal and structural domains." (Trichet, 2007)

Table 5: Mean of weighted absolute cyclical stress ($1/T \sum_t w_j |S_{j,t}^{cyc}|$) using different weighting schemes, in percent, 1999–2006

sentation in federal central banks can be rationalised on economic grounds. Papers by Berger and Müller (2007) and Hefeker and Gros (2002), which set-up a simple two-country models of a monetary union, show that a perfect match between economic size and voting rights is rarely optimal. Thus, the main conclusion to draw from this literature for our paper is that other weighting schemes than GDP shares to produce euro area aggregates might be relevant for the monetary policy decision process within the ECB Governing Council.

An alternative economic weighting scheme could be the capital key, which is defined as the fully paid-up subscriptions of euro area national central banks to the capital of the ECB. Given its definition as the unweighted average of the shares of the member countries in the total population and gross domestic product of the EU, the capital key’s high correlation with GDP weights is not surprising (see Figure 10). Apart from economic considerations, the weighting of country-specific information in the ECB’s Governing Council could also be influenced by institutional characteristics of the decision-making body. A rather extreme interpretation of the political process would be to assume that each country is represented equally and is only interested in optimising monetary policy for its own population. This would imply that each country-specific stress level receives the same weight. As an extension to this so-called “one country, one vote” principle, the statutes of the ECB state that the voting rights are equally allocated among the members of the Governing Council. Thus, each of the 6 members of the Executive Board and each national central bank governor has one vote. If we

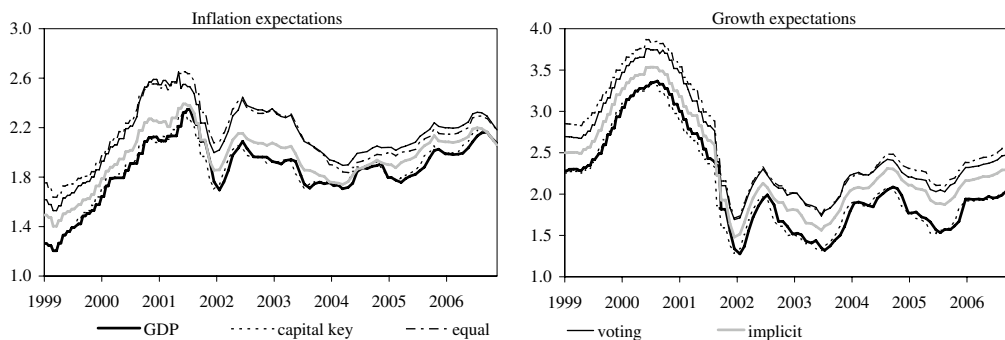

Figure 10: Weighting schemes for euro area aggregation

consider that decisions are taken by simple majority and if we assume that each member of the Governing Council is just a representative of his or her home country, we get a weighting scheme that takes the country distribution of voting rights into account. The basic difference to the equal weighting scheme is that countries like France, Germany, Italy and Spain, which were for most of the 1999-2006 period represented in the Executive Board, get a higher weight, whereas the opposite is true for countries like Belgium, Ireland and Portugal, which haven't been represented in the Executive Board yet. The common characteristic of the two institutional weighting schemes is that compared with their economic weights the three largest economies (France, Germany and Italy) are underrepresented, whereas the small economies (Austria, Belgium, Finland, Greece, Ireland, the Netherlands and Portugal) are overrepresented.

With each of these alternative weighting schemes we proceed as with our baseline GDP weights. We first aggregate country-specific expectations to euro area aggregates and estimate a euro area Taylor rule. Figure 11 shows that the evolution of expectations under the different weighting schemes is highly correlated; the pairwise correlation coefficients all lie above 90%. However, since under equal and voting weights the small countries with high trend growth rates of GDP and prices get a higher weight than their relative eco-

Figure 11: Area wide expectations using different weighting schemes

| Neutral real rate (α_{EA}) | 0.51** (0.06) | 0.30** (0.04) | 0.31** (0.05) | 0.41** (0.05) |
| Inflation expectations (β_{EA}) | 2.06** (0.36) | 1.90** (0.27) | 1.65** (0.30) | 1.99** (0.36) |
| Expected output growth (γ_{EA}) | 1.60** (0.17) | 1.20** (0.14) | 1.40** (0.17) | 1.52** (0.17) |

Notes: Heteroscedasticity and autocorrelation consistent standard errors shown in parentheses. * denotes significance at 10%, and ** significance at 5%.

Table 6: Estimation results for the Taylor rule using different weighting schemes, 1999–2006

conomic size, the aggregate evolution of inflation and growth expectations is shifted upwards. This shift is also reflected in the estimate for α_{EA} , which is lower than under the two economically based weighting schemes (see Table 6). Interestingly, the explanatory power of all Taylor rule regressions is as good as identical ($R^2 \approx 98.2\%$) and all the estimates are significant. The deviations of the other reaction coefficients from our baseline estimates are only of minor magnitude. While the coefficients on inflation expectations are somewhat higher, the coefficients on growth expectations are slightly lower in the case of equal and voting weights and marginally higher when the capital key is used for the aggregation to euro area expectations. Thus, the weighting scheme used to aggregate country-specific expectations to euro area expectations doesn't seem to matter for the validity of the Taylor rule model to describe the ECB's interest rate policy.

In a second step we calculate total stress for the euro area (see Figure 12)

and the country decomposition of its cyclical component (see Table 5). Not surprisingly, a weighting of the countries according to the capital key yields results, which are very close to those obtained under GDP weights. Again, total EMU stress has an upward trend, and the five largest member countries account on average for almost 80% of its cyclical component.

However, when countries are weighted equally or according to their voting rights, the synchronisation results point in the opposite direction. In these cases, smaller countries, which are given a weight higher than their economic share, automatically contribute more to the cyclical component of total EMU stress. As a consequence, the long-run pattern of cyclical EMU stress changes direction. Whereas we previously could not find evidence of a downward trend in overall cyclical stress, these other two weighting schemes result in a significant downward trend. Thus, when smaller countries receive a substantially larger weight as compared to their economic size, cyclical developments have become more synchronised since the introduction of the monetary union.

The result that the cyclical component of aggregate EMU stress is unevenly distributed across member countries, when we use the weights discussed so far, leads us to propose an alternative weighting scheme, which can be directly derived from our stress indicator. For a two country case where the weights attributed to country 1 and country 2 are w and $1 - w$, respectively, it can be shown that the cyclical components of stress can be written as

$$\begin{aligned}
S_{1,t}^{cyc} &= (w - 1)[\beta_{EA}(E_t\pi_{1,t+k} - \bar{\pi}_1 - E_t\pi_{2,t+k} + \bar{\pi}_2) + \\
&\quad + \gamma_{EA}(E_t\Delta y_{1,t+k} - \Delta\bar{y}_1 - E_t\Delta y_{2,t+k} + \Delta\bar{y}_2)] \\
S_{2,t}^{cyc} &= w[\beta_{EA}(E_t\pi_{1,t+k} - \bar{\pi}_1 - E_t\pi_{2,t+k} + \bar{\pi}_2) + \\
&\quad + \gamma_{EA}(E_t\Delta y_{1,t+k} - \Delta\bar{y}_1 - E_t\Delta y_{2,t+k} + \Delta\bar{y}_2)], \tag{7}
\end{aligned}$$

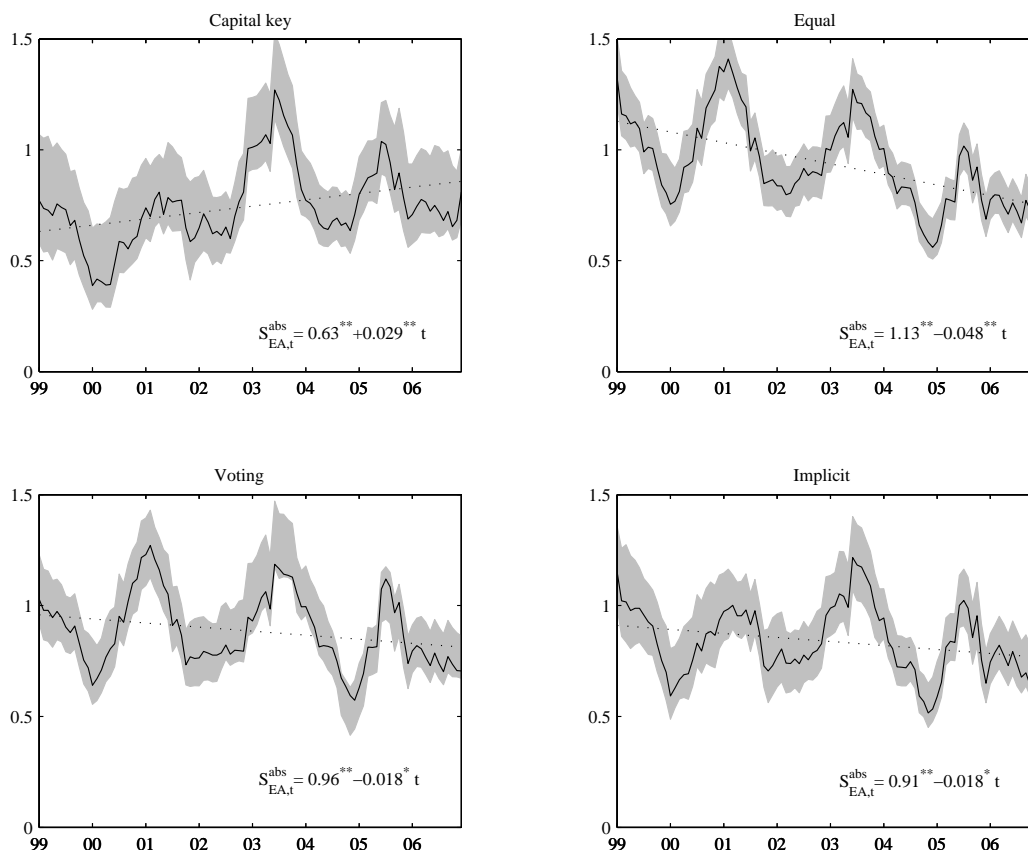

where we replaced the area wide aggregates in Equation (5) by their weighted country averages. As the two terms in brackets are identical, the following equality holds

$$wS_{1,t}^{cyc} = (w - 1)S_{2,t}^{cyc}, \tag{8}$$

which implies that the mean of weighted absolute cyclical stress should be equal across countries. Under the assumption that this equality also holds in the n -country case, the stress indicators can be used to derive the so-called implicit weights, we interpret as the actual representation of each member country in the ECB Governing Council.

In the actual political process, the small countries (Austria, Belgium, Finland, Greece, Ireland and Portugal) have implicitly received a rather large

Figure 12: Total stress in the euro area using different weighting schemes

Notes: The shaded areas are the 95 percent confidence intervals, which are calculated as the 0.025 and 0.975 quantile of the sampling distribution obtained from a bootstrap procedure with 1,000 replications. As the distribution of country-specific absolute stress is truncated at zero and hence skewed to the right, the confidence intervals around the means (which are computed using the point estimates of the baseline Taylor rule regression) are asymmetric. The dotted lines are linear trends of the means, whose estimated intercepts and (annualised) slopes are indicated in each graph. * denotes significance at 10%, and ** significance at 5%.

weight relative to their economic size. Thus, these countries are overrepresented in the ECB’s decision making process. When compared with the institutional weights (equal and voting) especially Austria and Belgium stand out, whose political influence turns out to be almost as pronounced as the German or the French. The three largest economies (France, Germany and Italy) are clearly underrepresented, when implicit weights are compared with economic weights. However, implicit weights are larger than those having been derived from the distribution of voting rights or from the “one country,

one vote” principle.

The area wide expectations that result from the use of implicit weights lie between those obtained when using economic weights and those obtained using institutional weights (see Figure 11). As a consequence, the estimate for α_{EA} is lower than with economic weights and higher than with institutional weights (see Table 6). The remaining coefficients of the Taylor rule do not appear to systematically differ from those of the baseline regression. Although this weighting scheme lies in between the economic and the institutional scenarios, the conclusion with respect to business cycle synchronisation remains clear cut. As before with institutional weights, aggregate euro area cyclical stress has significantly decreased over time.

5 Conclusions

In this paper we define monetary stress in a particular member country of the EMU as the difference between the ECB main refinancing rate and the policy interest rate that would prevail if that country would have been able to follow a for that country “optimal” monetary policy. Instead of extrapolating individual central bank behaviour before the introduction of the euro into the EMU period, we are the first to assume that the actual reaction function of the ECB is a good description of this “optimal” monetary policy at the country level. EMU countries voluntarily decided to participate in the monetary union, i.e. to adopt the institutional set up of the ECB. In this case, asymmetries in inflation and cyclical output developments across countries generate differences between the actual interest rate and the one that would prevail if the reaction function of the ECB were applied to the national level.

The reported monetary stress levels are sizeable. From a country perspective, on average interest rates should have been 2.8 percentage points higher in Ireland and 0.6 percentage points lower in Germany. The structurally lower inflation and growth rate kept stress levels positive in Germany throughout our sample. On the other hand—besides Ireland—Greece, Portugal and Spain mostly experienced negative stress levels. This has mainly been due to persistent higher inflation expectations in those countries. On top of that, in Greece and Ireland also growth expectations were higher. These differences are all of a structural nature and thereby not necessarily the focus of monetary policy. However, not only do stress levels vary considerably across the EMU countries, the variation over time is also quite substantial. For instance, although average stress levels were close to zero in the Netherlands and in Finland, rather pronounced cyclical patterns are

visible there. Overall, actual monetary policy of the ECB seems to have been rather appropriate for countries like Austria, Belgium, France and Italy. For Italy, higher inflation and lower growth neutralized each other.

When aggregating the country-specific monetary stress indicators to the euro area level, we first take a normative approach and weigh each country according to its economic size. The resulting indicator reveals that there are times in which output growth and inflation cycles are more synchronised across the euro area and, hence, the ECB policy is more in line with the preferences of each individual member country. However, the data does not reflect a general tendency of cycles to become more similar over time. Hence, we do not find evidence in favour of the euro area being a self-enforcing optimal currency area in such a scenario.

As noted by, e.g. Berger (2006), economic size does not represent the actual voting distribution of the ECB Governing Council.¹⁸ If we redo our analysis, but this time use e.g. the voting distribution within the Governing Council as weighting scheme, the resulting aggregate monetary stress indicator does point towards convergence of business cycles within the euro area. Apparently, when answering the question whether the euro area is a self-enforcing optimal currency area it is important to first take a stand on the actual weight countries are giving in the monetary policy decision process of the ECB.

Under the assumption that over time the burden of a common monetary policy is equally distributed amongst the member countries, our framework generates a weighting scheme in which mainly the larger economies (Germany, France, Italy and Spain) have on average been underrepresented in the political decision process as compared to their economic size. On the other hand, growth and inflation developments of the small and highly developed member states (Austria, Belgium, Finland) did—relative to their economic size—not bear a large part of the overall burden over the past eight years. Hence, this implicit weighting scheme shows quite some resemblance with our voting weighting scheme and indeed suggests a steady increase of business and inflation cycle synchronisation within the euro area. It implies a reduction of approximately 15 percent in monetary stress levels in the euro area during 1999-2006.

As a final note, in this paper we have only focussed upon monetary stress and thereby costs associated to differences in growth and inflation cycles

¹⁸According to Berger (2006) “The ECB is clearly an ‘extreme’ case . . . the misrepresentation indicator for the ECB’s Governing Council reached values about seven time higher than for the Fed’s FOMC or the Bundesbanks’s Zentralbankrat. Without reform, EMU enlargement could lead to even wider gaps between economic and political weights by the 2010s.”

within the euro area. Of course, there are also benefits associated to having a monetary union. For instance, it facilitates trade and fosters competition by enlarging markets. It is well possible that these and other benefits outweigh the costs associated with monetary stress.

Appendix

A Quantifying qualitative inflation expectations

The most widely used method for quantifying qualitative inflation expectations goes back to a paper by Carlson and Parkin (1975). Their method assumes that individual responses about the future value of a variable are based on the respondents’ subjective probability density function. Respondents report a variable to go up or down if the median of their subjective probability distribution lies above or below an indifference interval. The upper and lower boundary of the indifference interval which mark the so-called just noticeable difference are derived from the respondents’ aggregate

answers and the time-series properties of past realizations of the macroeconomic variable under consideration. Most crucially, Carlson and Parkin (1975) assumed the aggregate distribution to be normal with symmetric and time-invariant boundaries that are allowed to vary across countries. Additionally, they imposed that the average value of past realizations and the average value of expectations must be equal, which is typically referred to as the unbiasedness of expectations.

As these assumptions are rather restrictive a variant of the Carlson-Parkin method has been proposed by Heinemann and Ullrich (2006). In contrast to the standard Carlson-Parkin method they do not implicitly derive the just noticeable difference from the qualitative survey responses and from the statistical properties of the reference time-series, but from a special question in the survey in which they directly query the respondents' boundaries of the indifference interval. In practical terms, the respondents were asked to indicate the percentage point decrease (increase) of inflation that makes the respondent mark 'go down' ('go up') in the survey. Heinemann and Ullrich (2006) assume that these boundaries are constant over time and they estimate the lower boundary a_t to be -0.24 and the upper boundary b_t to be 0.22 .

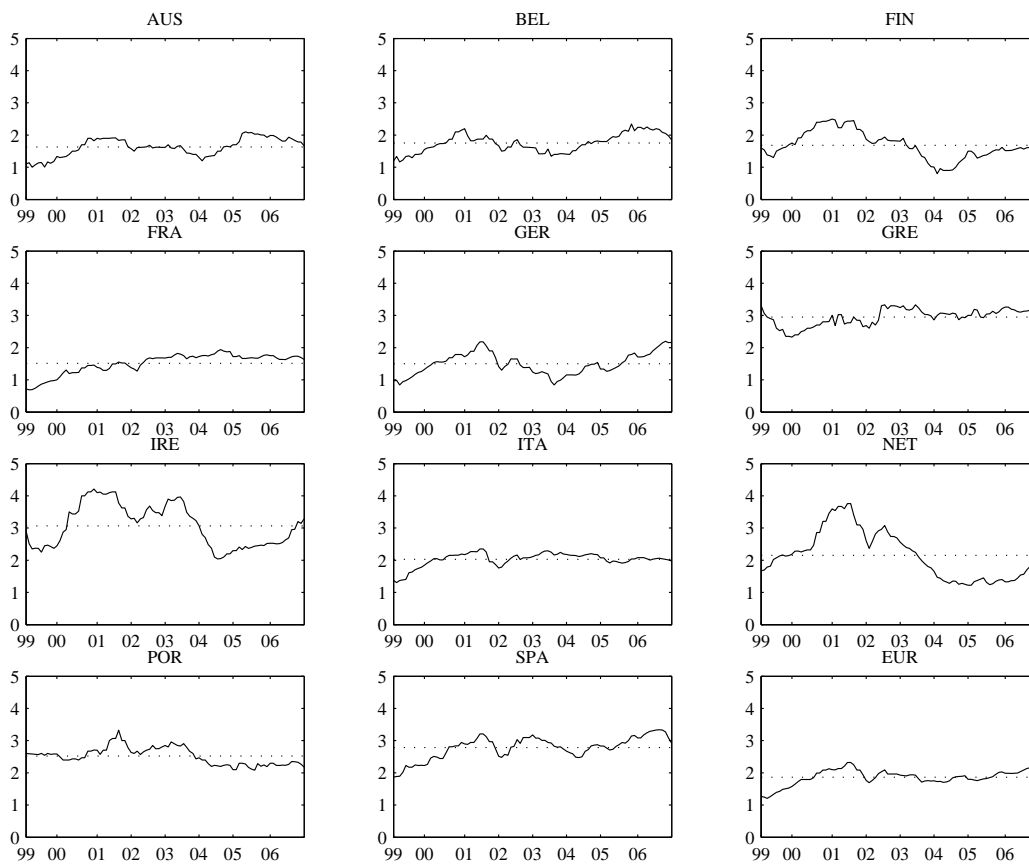

The formula for calculating the expected change in inflation is given by

$$E_t \Delta \pi_{t+k} = \frac{b_t \Phi^{-1}(\text{DOWN}_t) - a_t \Phi^{-1}(1 - \text{UP}_t)}{\Phi^{-1}(\text{DOWN}_t) - \Phi^{-1}(1 - \text{UP}_t)}, \quad (\text{A.1})$$

where Φ is the cumulative distribution function of an assumed standard normal variate, and UP_t and DOWN_t denote the percentage of the responses expecting a rise and a fall in inflation.
