# Airline Delay Propagation: A Simple Method for Measuring Its Extent and Determinants

## Abstract

This paper offers a simple approach for identifying propagated departure delays and measuring their contribution to arrival delays. Under our approach, a propagated departure delay occurs when the arrival delay of the inbound flight exceeds the subsequent flight's ground buffer. The size (or frequency) of such propagated delays relative to the size (or frequency) of arrival delays then measures the contribution of propagated delays to late arrivals. This approach differs from earlier attempts to quantify the contribution of delay propagation since it focuses on an individual flight and its immediate predecessor, without attempting to trace the sources of delay propagation back through the entire sequence of prior flights. The paper's empirical results show that the contribution of propagated departure delays to arrival delays depends on several key determinants.

# Airline Delay Propagation: A Simple Method for Measuring its Extent and Determinants

by

Jan K. Brueckner, Achim I. Czerny and Alberto A. Gaggero\*

## 1. Introduction

Delay propagation, where late arrival of an inbound flight leads to a late departure and then late arrival of the subsequent outbound flight, is the main cause of flight delays in the US, according to FAA data.<sup>1</sup> A literature has emerged in transportation engineering and economics studying delay propagation as part of a broader inquiry into the stochastic aspects of airline operations. Two papers in particular, Arikan, Deshpande and Sohoni (2013) and Kafle and Zou (2016), propose methods for measuring the extent of delay propagation.<sup>2</sup> These methods are ambitious, with the goal of quantifying the potential cascade of delay propagation through the entire sequence of daily flights operated by a given aircraft. In other words, a late inbound arrival may lead to a departure delay and then late arrival of the next flight, which may in turn lead to late departure of the subsequent flight, and so on. With this broad view, isolating the contribution of delay propagation to the on-time performance of any particular flight is complex analytically, making an empirical implementation correspondingly complex.

The goal of the present paper is to offer and make use of a simpler approach to quantifying delay propagation and its effects. Our approach has a limited purpose, which is to identify propagated departure delays for individual flights *without considering their ultimate sources*. In other words, we seek to determine whether a flight's late departure was caused by late arrival of the inbound flight, *without asking whether the inbound flight's lateness was itself caused by prior delay propagation*. This narrower focus, which looks at an individual flight and its immediate predecessor rather than the entire daily flight sequence, yields straightforward measures of the contribution of delay propagation.

---

\* We thank Hanxiang Zhang for assistance in compiling the weather data.

<sup>1</sup> See Figure 1 in Brueckner, Czerny and Gaggero (2021a).

<sup>2</sup> See AhmadBeygi et al. (2008), AhmadBeygi, Cohn and Lapp (2010), and Deshpande and Arikan (2012) for related papers. Kim and Park (2021) apply Kafle and Zou's (2016) methods to Korean airports.

Central to our exercise is the ability to identify propagated departure delays in the data by applying the theoretical scheduling models of BCG (2021a,b). The theory indicates that a propagated departure delay occurs when late arrival of the inbound flight, measured in minutes, exceeds the ground buffer for the subsequent flight, equal to minutes of extra scheduled ground time beyond the minimum feasible aircraft turnaround time (quantities that all can be measured in the data). The difference between the inbound delay and the ground buffer, when positive, equals minutes of propagated departure delay. A ratio based on this quantity, minutes of propagated departure delay divided by minutes of arrival delay, gives our measure of the contribution of propagated departure delays to late arrivals.

We also compute variants of this propagation measure that rely on flight counts at the route level rather than minutes of delay for individual flights. One variant equals the number of flights on a route having both a propagated departure delay and an arrival delay divided by the number of flights with an arrival delay. This route-level propagation measure is also adjusted to capture the contribution to arrival delays of moderate inbound arrival delays, which do not automatically lead to a late departures.

The ultimate goal of the paper is to explore how the contribution of propagated departure delays to arrival delays varies with route, airport, and airline characteristics. Our first finding is that this contribution is lower when the origin airport is a hub for the airline. Thus, airlines apparently seek to avoid propagated departure delays at their hubs, with such delays contributing more to arrival delays on flights from *non-hub* origins, where the inbound flight may be coming from a hub.<sup>3</sup> Another finding is that the contribution of propagated departure delays rises over the day, with flights later in the day affected more than earlier flights. This finding presumably reflects the cumulative effect of prior delays during the day, whose causes are a mixture of propagated delay and delays from other sources. A third finding is that propagated departure delays contribute more to arrival delays in the case of low-cost carriers than for other airlines, partly reflecting the quick turnarounds (short ground buffers) that are a feature of their business model.<sup>4</sup>

---

<sup>3</sup> Using a completely different methodology, Diana (2009) explores whether delay propagation is higher at concentrated airports, which are usually hubs.

<sup>4</sup> In addition to showing that low-cost carriers have short ground buffers, some of BCG's (2021a) regressions

These findings are presented late in the paper (in section 5), after we present preliminary regressions that validate the underpinnings of our approach, which is done in section 4. The first preliminary regression verifies that arrival delays for inbound flights do indeed create departure delays. This flight-level regression relates minutes of departure delay to minutes of inbound arrival delay, and the estimated positive relationship illustrates the source of propagated departure delays.<sup>5</sup> Next, we verify that an inbound arrival delay can indeed create an arrival delay for the subsequent flight, with the regression relating minutes of arrival delay to minutes of inbound arrival delay and showing a positive connection. We also present spline versions of these regressions, where the impact of the inbound arrival delay is allowed to be larger the greater its size relative to the ground buffer (a pattern that is confirmed).

Having validated the underpinnings of our approach, our next preliminary regressions explore the main connection of interest, the one relating arrival delays to departure delays and other covariates.<sup>6</sup> We present flight-level regressions showing that the relationship is slightly less than one-to-one, even when departure delays are decomposed into propagated delays and delays from other sources. The near one-to-one connection appears to reflect the difficulty of overcoming a departure delay by faster flying, as illustrated in additional regressions relating airborne time to departure delay, which have very small negative coefficients.

With the underpinnings of our approach verified and the connection between arrival and departure delays explored, we then return in section 5 to our measures that quantify the contribution of propagated departure delays to late arrivals. We present regressions relating the flight-level and route-level contribution measures to a host of covariates, as described above.

The present paper is an outgrowth of our earlier research on flight delays and schedule buffers (Brueckner, Czerny and Gaggero, 2021a,b; hereafter BCG). These papers developed theoretical models of how airlines choose the magnitudes of schedule buffers, which are partly designed to reduce the likelihood of delay propagation. The flight buffer is the amount by which scheduled flight time exceeds the minimum possible flight time, and ground buffer is the

---

indicate that their flight buffers are also short, potentially contributing to late inbound arrivals.

<sup>5</sup> Tan et al. (2021) carry out a similar exercise for Chinese airports, but are forced because of data limitations to rely on airport averages rather than information for individual aircraft.

<sup>6</sup> Wong and Tsai (2012) estimate somewhat similar regressions, using a hazard (survival-analysis) approach.

analogous component of ground time, as mentioned above. These models generated predictions relating the size of buffers to various determinants, and BCG (2021a) tested these predictions via regression analysis relating buffer sizes to route characteristics, time-of-day and month, airline identities, aircraft type, and previous flight-time variability.<sup>7</sup> They relied on voluminous US Department of Transportation data on the daily scheduled and actual flight and ground times for individual aircraft, and these same data are used in the present paper to generate and exploit measures of actual delay propagation.<sup>8</sup>

The plan of the paper is as follows. Section 2 explains the model-based derivations underlying the empirical work, and section 3 discusses the data. As mentioned above, section 4 presents preliminary empirical results, while section 5 presents the regressions showing how the arrival-delay contribution of propagated departure delays varies by route, airport and airline characteristics. Section 6 offers conclusions.

## 2. The propagated delay measures

This section of the paper uses the scheduling model of BCG to derive the relationships that underlie the subsequent empirical work. Section 2.1 derives the equation relating arrival delays to departure delays, which underlies several of the regressions reported in section 4. Section 2.2 derives the formula that relates propagated departure delay to inbound arrival delay and the ground buffer, which is used in quantifying the contribution of propagated departure delays to arrival delays in section 2.3.

### 2.1. Preliminaries

For each of the millions of flights in our 2018 data set, we have information on its scheduled and actual times of departure and arrival as well as information on the magnitude of the flight buffer and the ground buffer prior to the flight. Following BCG, let  $t_{d,i}$  and  $t_{a,i}$  denote the

---

<sup>7</sup> Eufrásio, Eller and Oliveira (2021) carry out a similar exercise.

<sup>8</sup> A collection of papers related to research on buffers focuses on the determinants of scheduled block (flight) times and the issue of schedule “padding,” where flight times expand in response to growing airport congestion and other sources of delays. See Sohoni, Lee and Klabjan (2011), Hao and Hansen (2014), Kang and Hansen (2017), Kang and Hansen (2018), Zhang, Salant and Van Mieghem (2018), Fan (2019), Forbes, Lederman and Wither (2019), Forbes, Lederman and Yuan (2019), Wang et al. (2019), and Yimja and Gorjidoz (2019). Following earlier work, a different line of inquiry is exemplified by Li and Jing (2021), who test for interconnections between delays at different airports, thus characterizing a “delay propagation network.” Fleurquin, Ramasco and Eguiluz (2013) carry out a similar exercise.

scheduled departure and arrival times for flight  $i$ , and let  $\widehat{t}_{d,i}$  and  $\widehat{t}_{a,i}$  denote the flight's actual departure and arrival times. The departure and arrival delays for flight  $i$ , denoted  $D_{d,i}$  and  $D_{a,i}$  are then given by

$$D_{d,i} = \widehat{t}_{d,i} - t_{d,i} \quad (1)$$

$$D_{a,i} = \widehat{t}_{a,i} - t_{a,i}. \quad (2)$$

Note that these delay expressions can be negative (with departures or arrivals being early), as they often are in the data.

To see the connection between arrival and departure delays, the determinants of flight times must be considered. The actual arrival time of flight  $i$  is the actual departure time plus the actual flight time, given by

$$\widehat{t}_{a,i} = \widehat{t}_{d,i} + m_i + \epsilon_i. \quad (4)$$

In (4),  $m_i + \epsilon_i$  is the actual flight time, equal to minimum feasible flight time  $m_i$  plus a positive random term  $\epsilon_i$  that accounts for the randomness of flight durations.

The scheduled arrival time  $t_{a,i}$  equals the scheduled departure time  $t_{d,i}$  plus the scheduled flight time, which equals the minimum flight time  $m_i$  plus the flight buffer  $b_{f,i}$ . With  $t_{a,i}$  thus equal to  $t_{d,i} + m_i + b_{f,i}$ , arrival delay is equal to

$$\begin{aligned} D_{a,i} &= \widehat{t}_{a,i} - t_{a,i} = \widehat{t}_{d,i} + m_i + \epsilon_i - (t_{d,i} + m_i + b_{f,i}) \\ &= D_{d,i} + \epsilon_i - b_{f,i}, \end{aligned} \quad (5)$$

using (2). Therefore, arrival delay equals departure delay plus the random flight-duration term minus the flight buffer. With the random term held fixed, arrival delay then rises in one-for-one fashion as departure delay increases. But since the random factor is not fixed in reality, and since the buffer  $b_{f,i}$  varies across flights, this one-for-one relationship is likely to hold only approximately.

## 2.2. Propagated departure delay

The discussion now turns to the determinants of departure delay,  $D_{d,i}$  in (5). In BCG (2021a), the only cause of a departure delay is late arrival of the inbound flight. In other words, a propagated departure delay is the only kind of departure delay in their model. In their follow-up paper, BCG (2021b) realistically added random shocks to the ground time prior to a flight, which provide another source of departure delays.

Suppressing such shocks to focus on propagated departure delays, let  $t_{a,i-1}$  and  $\hat{t}_{a,i-1}$  denote the scheduled and actual arrival times for the inbound flight (flight  $i - 1$ ). Then, the inbound arrival delay is

$$D_{a,i-1} = \hat{t}_{a,i-1} - t_{a,i-1}. \quad (6)$$

Furthermore, let the scheduled ground time prior to flight  $i$  be denoted  $t_{g,i}$  and let the minimum flight turnaround time be denoted  $\bar{t}_{g,i}$ . Flight  $i$ 's ground buffer then equals

$$b_{g,i} = t_{g,i} - \bar{t}_{g,i} > 0, \quad (7)$$

being equal to the excess of scheduled ground time above the minimum turnaround time, as noted above. The minimum turnaround is computed from the data and is specific to airports and aircraft types.

To derive the departure delay in (5), note that the actual departure time of flight  $i$  equals

$$\hat{t}_{d,i} = \max\{t_{d,i}, \hat{t}_{a,i-1} + \bar{t}_{g,i}\}. \quad (8)$$

To understand (8), note that  $\hat{t}_{a,i-1} + \bar{t}_{g,i}$  is the earliest possible departure time for flight  $i$ , equal to the arrival time of the inbound flight plus the minimum aircraft turnaround time. If the inbound flight arrives on time ( $t_{a,i-1} = \hat{t}_{a,i-1}$ ), then this expression equals  $t_{a,i-1} + \bar{t}_{g,i} < t_{a,i-1} + t_{g,i} = t_{d,i}$ , being less than the scheduled departure time (note  $\bar{t}_{g,i} < t_{g,i}$ ). The max in (8) then equals the first  $t_{d,i}$  argument, so that flight  $i$  departs on time. But if the reverse inequality holds, so that  $\hat{t}_{a,i-1} + \bar{t}_{g,i} > t_{d,i}$ , then the flight's earliest possible departure time exceeds the scheduled departure time, and flight  $i$  departs late.

To derive the magnitude of the resulting propagated departure delay, the scheduled departure time  $t_{d,i}$  is subtracted from both sides of (8), which becomes

$$D_{d,i} = \hat{t}_{d,i} - t_{d,i} = \max\{0, \hat{t}_{a,i-1} + \bar{t}_{g,i} - t_{d,i}\}. \quad (9)$$

Adding and subtracting  $t_{a,i-1}$  from the second max expression in (6) yields

$$\begin{aligned} D_{d,i} &= \max\{0, \hat{t}_{a,i-1} - t_{a,i-1} + t_{a,i-1} + \bar{t}_{g,i} - t_{d,i}\} \\ &= \max\{0, D_{a,i-1} + t_{a,i-1} + \bar{t}_{g,i} - t_{d,i}\} \\ &= \max\{0, D_{a,i-1} + t_{a,i-1} + t_{g,i} + \bar{t}_{g,i} - t_{g,i} - t_{d,i}\} \\ &= \max\{0, D_{a,i-1} - b_{g,i}\}, \end{aligned} \quad (10)$$

where the last equality comes from adding and subtracting  $t_{g,i}$  in the previous line and using  $t_{d,i} = t_{a,i-1} + t_{g,i}$  and  $t_{g,i} - \bar{t}_{g,i} = b_{g,i}$ . Therefore, the departure delay for flight  $i$  equals the inbound arrival delay minus the ground buffer if this quantity is positive, equaling zero otherwise. This result allows us to measure propagated departure delays in our data.

### 2.3. Measuring the arrival-delay contribution of propagated departure delays

As noted above, sources beyond delay propagation contribute to departure delays in actual flight operations, and the notation of the model must be adjusted to reflect this reality. Accordingly, let expression  $D_{d,i}$  in (10) be renamed  $D_{d,i}^{prop}$  to reflect its measurement of propagated departure delay. Also, let  $D_{d,i}^{tot}$  equal total minutes of departure delay from all sources, and let  $D_{d,i}^{other} = D_{d,i}^{tot} - D_{d,i}^{prop}$  denote minutes of departure delay from sources other than propagation.

Since our data allow measurement of the actual and scheduled arrival times of all flights along with magnitude of the ground buffer for individual flights,  $D_{d,i}^{prop}$  in (10) can be computed along with  $D_{a,i}$  in (2). To measure the contribution of propagated departure delays to late arrivals, we then form the ratio

$$R_i^{flight} = \frac{D_{d,i}^{prop}}{D_{a,i}} = \frac{\text{minutes of propagated departure delay for flight } i}{\text{minutes of arrival delay for flight } i}, \quad (11)$$

where the *flight* superscript on  $R$  indicates that the ratio is measured at the individual flight level. Note that  $R_i^{flight}$  captures the share of just one source, propagated departure delay, in minutes of arrival delay. Additional sources are minutes of departure delay caused by factors other than propagation along with random elements (weather, unanticipated congestion) that affect flight times (note that flight time equals airborne time plus taxi-in and taxi-out times).

While  $R_i^{flight}$  is computed for each flight in our data set, it is also possible to compute an  $R$  ratio at the route level, where a route consists of two endpoint airports connected by nonstop service. Rather than using minutes of delay, this route-level aggregation simply counts the number of flights on a route with both propagated departure delay and arrival delay along with the number of flights with arrival delay, yielding

$$R_r^{route} = \frac{\# \text{ route-}r \text{ flights with propagated departure delay and arrival delay}}{\# \text{ route-}r \text{ flights with arrival delay}}, \quad (12)$$

where  $r$  denotes the route and an arrival delay occurs when  $D_{a,i} > 15$  minutes, following the FAA definition. Among flights with arrival delay,  $R_r^{route}$  thus gives the share that also had a propagated departure delay. In actuality, the route-level aggregation is finer than indicated in (12), with aggregation occurring at the route  $\times$  week (or month) level.

While the  $R_r^{route}$  tells whether a late-arriving flight also had a propagated departure delay, it does not net out the other factors that may have contributed to the late arrival. However, an adjusted measure can be constructed that does so. To produce this adjusted  $R$  ratio, which better captures the share of late arrivals caused solely by propagated departure delays, we compute the share of flights at the route level with no departure delay that also experienced an arrival delay, equal to  $A_r^{route}$ . The adjusted ratio is then  $R_r^{adj} = (1 - A_r^{route}) \times R_r^{route}$ , where the share of flights with no departure delay that arrived late is netted out.<sup>9</sup> However, because  $A_r^{route}$  is on average near zero, this adjustment has little effect. The near-zero value shows that flights without a departure delay are very seldom late (with  $D_{a,i} > 15$  minutes), so

---

<sup>9</sup> Specifically,

$$A_r^{route} = \frac{\text{number of route-}r \text{ flights without departure delay but with arrival delay}}{\text{number of route-}r \text{ flights without departure delay}}.$$

that arrival delays are almost exclusively due to departure delays. This conclusion can be seen in a different way by replacing  $D_{d,i}^{prop}$  in the ratio in (11) with  $D_{d,i}^{tot}$ , which yields a modified ratio whose average value is close to 1 (equal to 0.85), showing that arrival delay minutes on average approximately equal minutes of total departure delay.

If the inbound flight experiences an arrival delay smaller in magnitude than the ground buffer, then a propagated departure delay as we have defined it does not occur. However, the shortening of the available turnaround time as a result of the inbound delay offers a greater chance for stochastic ground-time factors to make the flight depart late. As a result, it could be argued that a moderate inbound arrival delay could generate an indirect propagated departure delay via this channel. To capture the arrival-delay contribution of departure delays from such indirect propagation, the following variant of  $R_r^{route}$  is computed:

$$\tilde{R}_r^{route} = \frac{\# \text{ route-}r \text{ flights with } 0.5b_g < D_{a,i-1} \leq b_g, \text{ with departure delay, and with arrival delay}}{\# \text{ route-}r \text{ flights with arrival delay}} \quad (13)$$

This ratio equals the share of flights with an arrival delay that have both a departure delay and a moderate inbound arrival delay (between half and the full ground buffer), which may have contributed to the departure delay.

### 3. Data description

The sample used in this paper covers US domestic airline operations for the year 2018. It is constructed by combining information from the US Department of Transportation and Weather Underground.<sup>10</sup>

The USDOT data is from the ‘Marketing Carrier On-Time Performance’ dataset, which at the aircraft level, uniquely identified by the aircraft’s tail number, provides information on the carrier operating the flight, the origin and destination airports, the departure date, the scheduled and actual departure and arrival times, the taxi-out and taxi-in times, and the airborne time (flights to and from foreign destinations are not covered). From this initial dataset, we remove canceled or diverted flights as well flights from/to US Commonwealth areas

---

<sup>10</sup> See [https://www.transtats.bts.gov/Fields.asp?gnoyr\\_VQ=FGK](https://www.transtats.bts.gov/Fields.asp?gnoyr_VQ=FGK) for the former and <https://www.wunderground.com> for the latter source of data.

and Territories. Flights with an arrival or departure delay greater than 120 minutes are also excluded to prevent outliers from affecting our results.<sup>11</sup>

Our regressions have a panel structure, with the time dimension corresponding to the days of 2018 and the cross sectional dimension corresponding to aircraft with different tail numbers. Accordingly, the regressions include date fixed effects as well as tail-number fixed effects.

To calculate the ground buffer using (7), we first compute the scheduled ground time  $t_{g,i}$  that separates flight  $i$  and flight  $i-1$  in the sequence of flights operated by the observed aircraft during the day. Then we calculate the minimum turnaround time as the shortest actual ground time observed across all aircraft of a given type using the turnaround airport. The ground buffer for flight  $i$  is then obtained by subtracting this minimum feasible ground time from the scheduled ground time, as in (7).<sup>12</sup> Finally, as in BCG (2021a), we exclude from the sample aircraft that operate more than 8 flights during the day.<sup>13</sup>

The weather data are obtained from Weather Underground, a commercial meteorological service that provides weather reports at each airport roughly every half-hour or every hour, depending on the airport. Among various meteorological metrics, each weather report shows the general weather condition (i.e., sunny, cloudy, rainy, etc.) and the temperature, which are two relevant pieces of information used in the regressions. The weather data are included in our sample by matching the actual take-off and landing times of each flight with the latest available weather report at the origin and destination airports, respectively. For example, if a flight leaves at JFK at 9:15 AM and arrives at LAX at 12:15 PM, then JFK hourly weather at 9:00 AM and LAX weather at 12:00 PM are the origin and destination weather observations

---

<sup>11</sup> We also excluded flights below the first percentile of the arrival or departure delay distributions (very early arrivals or very early departures).

<sup>12</sup> Since the Marketing Carrier On-Time Performance dataset does not include international flights, except those from/to US Commonwealth areas and Territories, we restrict the ground buffer to be not greater than 200 minutes, to exclude possible incomplete records that may arise when an aircraft flies to a non-domestic destination (e.g., Canada or Mexico, returning to the same US airport) between two domestic flights (the resulting time gap would be incorrectly identified as a ground buffer). Furthermore, in order to have confidence in the accuracy of the observed minimum ground time used in the buffer computation, we require that the number of observations used to generate it is at least equal to 30.

<sup>13</sup> This restriction mostly removes ‘ping-pong’ flights, which are flights that, multiple times in a day, operate a very short-haul route linking a hub to non-hub airports (e.g., Hawaiian flights between Honolulu and the other Hawaiian islands). Although these flights are generally characterized by a short ground buffer, delay propagation is not an issue.

for the flight.<sup>14</sup>

Table 1 presents summary statistics for the sample, which contains more than 4.2 million flights. The mean arrival delay, listed in the second row, is  $-0.61$  minutes, reflecting the fact that, despite widespread concerns about delays, most flights arrive early. This fact is also illustrated in the darkly shaded histogram in the first panel of Figure 1, which shows that the mode of the delay distribution lies in the negative range (the minimum is  $-49$  minutes). A long positive tail exists, however, which is truncated at 120 minutes per our sample restriction.

As seen in Table 1, the mean (total) departure delay is positive at 4.53 minutes. The lightly shaded histogram in the first panel of Figure 1, which shows departure delays, reveals that negative delays are again common, occurring when all passengers have boarded and an early departure is otherwise feasible. But since aircraft cannot leave too far in advance of their scheduled departure, the minimum departure delay is  $-19$  minutes, with most values above  $-10$  minutes.

The difference between the arrival and departure-delay distributions is shown in the second panel of Figure 1, which confirms that the distributions have very similar positive tails while showing that, in the negative range, departure delays are more concentrated near zero. Returning to Table 1, the first row shows that the mean arrival delay of  $-2.24$  minutes for previous flights (flight  $i - 1$ ) is even more negative than the flight- $i$  mean, a consequence of the fact that previous flights are earlier in the day on average, when delays are less common.

Propagated departure delays, given by  $D_{d,i}^{prop}$  in (10), have a mean of 1.73 minutes (by definition, they must be positive) and maximum of 113 minutes. Other departure delays, given by  $D_{d,i}^{other}$  and equal to the difference between total and propagated delays, have a mean of 2.80 minutes and a maximum at the truncated value of 120 minutes.

The remaining rows of Table 1 show summary statistics for the different versions of the  $R$  ratio, which capture the contribution of propagated departure delays to arrival delays. The flight-based  $R_i^{flight}$ , which is defined only for positive arrival delay, has a mean of 0.127, showing that minutes of propagated departure delay are on average about 13% of arrival-delay minutes. Thus, for flights that arrive late, the contribution of propagated departure delay is

---

<sup>14</sup> A similar approach is adopted by Bubalo and Gaggero (2015, 2021).

fairly modest in size when delays are measured in minutes.

Note that, while one would expect  $R_i^{flight}$  to be less than 1, its maximum value is 44, reflecting an unusual situation where an appreciable propagated departure delay was almost entirely overcome, leading to a small arrival delay. However, cases with  $R_i^{flight} > 1$  are relatively rare, accounting for just 2.5% of the 1,432,430 observations with a positive arrival delay, and among these observations, the median value is 1.25, not far above 1.

The next row of Table 1 shows the route-based  $R$ , computed at the route  $\times$  month level. The mean value of 0.354 indicates that among flights with an arrival delay longer than 15 minutes, 35% had a propagated departure delay. The subsequent row of the table shows  $R_r^{route}$  instead computed at the route  $\times$  week level, which has a somewhat smaller mean equal to 0.271.

The final two rows of the table show the route-level  $R$  variables based on moderate inbound arrival delays, computed at the month and week levels. The values are smaller than those of the  $R_r^{route}$  variables, indicating that the combination of a moderate inbound arrival delay and a departure delay is less common than a propagated departure delay as a cause of late arrival.

Summary statistics for our other covariates are shown in Table A1 in the appendix. The weather and hub variables are self explanatory, while the congestion variables are equal to airport traffic in the hour of a flight's arrival or departure divided by the number runways (see BCG, 2021a) and the competition variable equals the number of airlines competing nonstop on the route.

Table 2 shows how the mean  $R$  ratios vary by airline, carrier type, and the origin airport's size as well as its hub and slot-control status. The flight-based  $R$  in the first column ranges between 0.061 (for Hawaiian) and 0.196 (for Frontier). Because Hawaiian operates mostly long distance flights where aircraft turnaround is not a large factor in delays, its small  $R$  may make sense. By contrast, the high  $R$  values for Allegiant, Frontier, and Jet Blue could reflect the small ground buffers (and thus quick turnarounds) favored by low-cost carriers, which raise the likelihood of propagated departure delays. While Southwest and Spirit have lower  $R$  values, low-cost carriers on average have higher  $R$  values than legacy carriers, as seen in the next panel of the table. Consistent with this difference, the three big network carriers (American, Delta

and United) have relatively low  $R$  values, consistent with their less-aggressive turnaround scheduling. The regressions presented in section 5 confirm that, when controlling for other factors, LCCs continue to have higher  $R$  values than other carriers.

The magnitudes of the  $R$  variables also depend on airport characteristics, the most important of which is the hub status of the origin airport. As can be seen in first column, non-hub origins have higher flight-based  $R$  values than hub origins, a pattern again confirmed by our section-5 regressions. Thus, the contribution of propagated departure delays to late arrivals is greater for flights with non-hub origins. Column 1 of the table also shows that the mean  $R$  varies directly with origin-airport size, although this variation may be mainly capturing a hub/non-hub difference. By contrast, slot-controlled airports (which tend to be large) have higher  $R$  values.

Turning to the other columns of Table 2, the means of the route-level variable  $R_r^{route}$  at both the month and the week level show rankings across airlines similar to the ranking in the first column. The effects of airport characteristics are also similar, except that slot control now has little effect. By contrast, the  $\tilde{R}_r^{route}$  variable, designed to capture the arrival-delay contribution of indirect propagated departure delays, shows different patterns. The range of values in the third column, which shows the month-based measure, is narrower than in column 2, and the ranking across carriers differs. Now, the LCC value is only slightly larger than the legacy value, and hub/non-hub and large/small patterns are reversed, with  $\tilde{R}_r^{route}$  larger at hubs and at large airports. This measure, which attempts to capture the contribution of indirect propagated departure delay, thus varies across airports and airlines differently than the variable  $R_r^{route}$ , which is based on a strict definition of propagated departure delay and thus captures the direct effect. Further discussion of these differences is presented in section 5.

#### 4. Preliminary regressions

As explained in the introduction, this section of the paper reports the results of preliminary regressions that have two purposes. The first is to validate the underpinnings of our approach by showing that an inbound arrival delay can lead to a late departure and late arrival for the subsequent flight. The second purpose is to explore the connection between departure delays

and arrival delays, showing that the two are closely linked.

The first two columns of Table 3 confirm the basic mechanism of delay propagation by relating departure delay in minutes to minutes of arrival delay for the inbound flight along with a host of control variables. While column 1 shows the expected positive effect in an equation with a single inbound delay variable (whose coefficient is 0.302), column 2 allows the effect of the inbound delay to depend on its size relative to the ground buffer  $b_{g,i}$ .

This second regression is a continuous spline specification that allows the inbound delay coefficient to be different for the cases where  $D_{a,i-1} \leq 0.5b_{g,i}$  ( $D_{a,i-1}$  smaller than half the buffer),  $0.5b_{g,i} < D_{a,i-1} \leq b_{g,i}$  (between half the buffer and the full buffer), and  $b_{g,i} < D_{a,i-1}$  (greater than the buffer).<sup>15</sup> Since this latter case is the one where a propagated departure delay exists according to our definition, we expect the third coefficient to be the largest of the three and near 1. This is exactly what the regression shows, with an extra minute of inbound arrival delay leading to 0.872 additional minutes of departure delay when the inbound delay is already larger than the ground buffer. By contrast, when the inbound arrival delay is less than half the size of the buffer, an additional minute of inbound delay leads to a negligible increase in departure delay (0.040 minutes), as expected. But in the intermediate case, where the inbound arrival delay is moderate, lying between half the ground buffer and the full buffer, an extra minute raises departure delay by 0.535 minutes. While the inbound delay in this case is not large enough to not automatically create a departure delay, it narrows the window for avoiding a delay, making it more likely that other factors will tip the flight into a situation where it departs late. This effect is seen in the moderate magnitude of the estimated coefficient, and its existence provides the motivation for the  $\tilde{R}_r^{route}$  ratio.

While these regressions confirm the mechanism leading to a propagated departure delay,

---

<sup>15</sup> If the three spline regimes are given by  $D_{d,i}^{tot} = \alpha + \beta D_{a,i-1}$ ,  $\theta + \gamma D_{a,i-1}$ ,  $\mu + \tau D_{a,i-1}$ , with continuity required at the break points  $G_1 = 0.5b_{g,i}$  and  $G_2 = b_{g,i}$ , then the departure delay regression is

$$\begin{aligned} D_{d,i}^{tot} &= \alpha + \beta[(D_{a,i-1} - G_1)I_1 + G_1] \\ &\quad + \gamma[(D_{a,i-1} - G_2)I_2 + (G_2 - G_1)(1 - I_1)] \\ &\quad + \tau(D_{a,i-1} - G_2)(1 - I_1 - I_2), \end{aligned}$$

where  $I_1 = 1$  if  $D_{a,i-1} \leq b_{g,i}$  and zero otherwise and  $I_2 = 1$  if  $0.5b_{g,i} < D_{a,i-1} \leq b_{g,i}$  and zero otherwise. The estimated  $\beta$ ,  $\gamma$ , and  $\tau$  coefficients are shown in column 2.

the last two columns of Table 3 study a more-indirect linkage by relating the arrival delay of flight  $i$  ( $D_{a,i}$ ) to the inbound arrival delay of the previous flight ( $D_{a,i-1}$ ). The first regression has a single delay coefficient (equal to 0.113), while the second regression again is a spline specification. The pattern of coefficients is similar to that in column 2, with the magnitude of the third coefficient showing that an increase in  $D_{a,i-1}$  when it is already larger than  $b_{g,i}$  leads to an additional 0.695 minutes of arrival delay. Since arrival delay is less directly linked to  $D_{a,i-1}$  than is departure delay, it is natural that this coefficient is smaller than the 0.872 coefficient in column 2. The first coefficient in column 4 is actually negative, while the second is moderate and size but smaller than the corresponding coefficient in column 2.

The coefficients of the control variables in columns 1 and 2 show that departure delays are higher for longer flights, at hub origins, when congestion is high at both endpoints, when there are more competitors on the route, and that delays are mostly higher later in the day (early morning is the default) and when weather is bad at either endpoint. The effects of the control variables on arrival delays are qualitatively very similar, except that delays are lower when the flight is longer and a hub is the destination (the competition effect is also absent). Evidently, airlines make special efforts to have flights arrive on time at their hubs so as not to disrupt network operations. Note that, in addition to weather at the origin airport, destination weather can affect departure delays if flight controllers impose a “ground hold” at the origin. Similarly, weather at both endpoints, which affects takeoffs and landings, will matter for arrival delays.

Table 4 serves the second purpose mentioned above by presenting regressions that show the connection between arrival delays and departure delays. These regressions, which follow equation (5) in section 2, provide quantitative evidence on the arrival-delay impact of propagated and other departure delays. This impact underlies the propagated-delay contribution measures  $R_i^{flight}$  and  $R_r^{route}$ , whose determinants are explored in next section of the paper.

Column 1 of Table 4 shows that total departure delay translates almost one-for-one into arrival delay, with an extra minute of total departure delay leading to 0.876 extra minutes of arrival delay. Column 2 decomposes the total departure delay effect by allowing propagated departure delay ( $D_{d,i}^{prop}$ ) and other departure delay ( $D_{d,i}^{other}$ ) to have different coefficients. As

can be seen, the  $D_{d,i}^{prop}$  coefficient is the smaller of the two, indicating that an extra minute of propagated departure delay leads to 0.765 additional minutes of arrival delay, while an extra minute of other departure delay leads to 0.909 additional minutes of arrival delay. The coefficients are statistically different from one another, as the test at the bottom of the table indicates. These results evidently show that airlines work harder to overcome the arrival-delay impact of a departure delay when the departure delay is propagated rather than caused by other factors. Carriers perhaps view lateness due to propagated departure delays as more damaging to their reputations, although the coefficient difference is not large.

Column 3 shows a logit version of the same regression, with a flight counted as late if  $D_{a,i}$  is greater than 15 minutes. As can be seen, the  $D_{d,i}^{prop}$  coefficient is once again smaller than the  $D_{d,i}^{other}$  coefficient, again suggesting that airlines try harder to offset propagated departure delays than delays from other causes.

The results from columns 1 and 2 of Table 4 suggest that it is hard to overcome departure delays, which translate almost one-for-one into arrival delays. The most obvious way of overcoming a departure delay is for the aircraft to fly faster en route, and the one-for-one relationship suggests that this potential remedy is not able to help much.<sup>16</sup> The regressions in Table 5 provide explicit evidence for this conclusion by relating airborne time at the individual flight level to total departure delay. Regardless of whether the magnitude of  $D_{d,i}^{tot}$  is unrestricted, constrained to be positive, or constrained to be greater than 15 minutes, the regressions show that an extra minute of departure delay leads to very small reduction in airborne time (between 0.048 and 0.069 minutes). Thus, flying faster does not provide much scope for overcoming departure delays.<sup>17</sup>

Returning to Table 4, column 4 provides a more flexible specification that allows a departure delay's effect on arrival delay to depend on the magnitude of the delay. The regression

---

<sup>16</sup> Aktürk, Atamtürk and Gürel (2014) analyze increases in aircraft speed as a means of offsetting departure delays, recognizing the penalty of higher fuel consumption.

<sup>17</sup> The airport-specific control variables in Table 5 are measured only for the destination, which is appropriate since, once a flight is airborne, origin characteristics no longer matter. A greater distance naturally increases airborne time, while time is longer when the destination is congested or has bad weather (although low temperatures reduce it). A hub destination reduces airborne time, as does the presence of more competitors on the route, and airborne time is lower early and late in the day.

is a two-regime continuous spline, where the break point ( $K_r$ ) equals the mean minus the minimum airborne time on the route, on the belief that delays shorter than this value can be more easily made up by faster flying.<sup>18</sup> The mean value of  $K_r$  is 19.5 minutes. The results in column 4 show that, when  $D_{d,i}^{tot}$  is less than  $K_r$ , an extra minute of departure delay translates into only an additional 0.113 minutes of arrival delay. But when  $D_{d,i}^{tot}$  is larger than  $K_r$ , an extra departure delay minute leads to 1.026 additional minutes of arrival delay. The coefficient values naturally bracket the 0.876 coefficient in column 1, which can be viewed as a weighted average of the spline coefficients. This regression suggests that long delays, which translate one-for-one into incremental arrival delays, are the source of Table 5’s evidence that departure delays are hard to make up by faster flying. Evidently, greater speed or other actions can mostly offset shorter departure delays.

The control-variable coefficients in Table 4 almost always have the same signs and significance as the coefficients in columns 3 and 4 of Table 3, with arrival delays higher (lower) when the origin (destination) is a hub, higher when either endpoint is congested, when the route has more competitors, when the flight occurs later in the day, and when the weather at either endpoint is bad. As in Table 3, arrival delays are lower for long-distance flights, which may offer the airline a better chance to offset a departure delay. This relationship is shown in Figure 2, which graphs arrival delay as a function of departure delay (using mean values), with each curve showing a different distance range. As can be seen, a longer distance range leads to a lower-level curve.

Finally, it is useful to consider an econometric issue that may influence the magnitude of the departure-delay coefficients in Table 4. Recall from equation (5) that arrival delay equals departure delay plus the random flight-duration term minus the flight buffer  $b_{f,i}$ , with the latter factors constituting part of the regression error term in the Table 4’s regressions. It is possible, however, that carriers adjust the flight buffer upward in response to repeated departure delays, so as to reduce arrival delays. If so, the  $-b_{f,i}$  component of the regression

---

<sup>18</sup> If the two spline regimes are given by  $D_{a,i} = \alpha + \beta D_{d,i}^{tot}$ ,  $\theta + \gamma D_{d,i}^{tot}$  with continuity required at the break point  $K_r$ , then the regression is

$$D_{a,i} = \alpha + \beta[(D_{d,i}^{tot} - K_r)I + K_r] + \gamma(D_{d,i}^{tot} - K_r)(1 - I)$$

where  $I = 1$  if  $D_{d,i}^{tot} \leq K_r$  and zero otherwise.

error term is negatively correlated with the departure-delay covariate, biasing its coefficient downward. Therefore, the fact that the 0.876 coefficient in column 1 is less than 1 may reflect this downward bias, rather than revealing a true arrival-delay impact slightly less than one-for-one. However, since this estimated coefficient is very close to one, the issue may be mostly moot. One might argue that the bias could be eliminated by including the flight buffer (which we can measure) as an additional covariate in the arrival-delay regressions. But since the buffer is endogenous (being chosen by the airline schedulers) and suitable instruments are not apparent, this remedy would simply replace one econometric issue with a new one.

## 5. Determinants of the arrival-delay contribution of propagated departure delays

Having explored the interconnections among inbound arrival delays, departure delays, and subsequent arrival days in sections 3 and 4, this section presents regressions showing the determinants of the  $R$  ratios, which capture the contribution of propagated departure delays to arrival delays. Table 6 presents the regression results when the flight-based  $R$  ratio is the dependent variable. Column 1 shows the basic regression, while columns 2–4 show the results under several sample restrictions. Referring to column 1, the results show that the contribution of propagated departure delays increases over the day, with the time-of-day coefficients rising monotonically across the time intervals. Recalling that its mean in Table 1 is 0.13, the increase in  $R_i^{flight}$  moving from morning to evening, equal to  $0.178 - 0.42 = 0.136$ , is roughly equal to the mean value. Thus, time-of-day has a large effect on the contribution of propagated departure delays, apparently reflecting the cumulative effect of delays over the day, which make a propagated delay more likely near the day’s end. Switching from a non-hub to a hub origin also has a large negative effect on the contribution of propagated departure delays, reducing  $R$  by 0.104, an amount just below the mean (matching the pattern in Table 2). Thus, propagated departure delays contribute less to arrival delays for hub-departing flights, with their contribution greater at smaller, non-hub origins.

A hub destination, by contrast, raises the contribution of propagated departure delays, evidently through a reduction in arrival delays (as seen in Tables 3 and 4), which reduces the

denominator of the  $R$  ratio, raising the ratio's magnitude. The effect is smaller in absolute terms, however, than that of a hub origin.

As for the other covariates, distance in column 1 of Table 6 has a positive effect on  $R_r^{route}$ , the effects of airport congestion are mixed, competition has no effect, and the weather variables have mostly negative coefficients. Bad weather at either endpoint generates arrival delays for a host of reasons, thereby reducing the contribution of propagated departure delays and apparently yielding negative effects on the  $R$  ratio.

The results in columns 2–4 of Table 6, which are based on various sample restrictions, are similar to those in column 1, showing the robustness of those findings. While arrival delays are restricted to be positive in column 1, further restricting them to exceed 15 minutes, as in column 2, has very little effect on the estimated coefficients despite a more than 50% reduction in the sample size. Returning to positive arrival delays but requiring the total departure delay to be positive, as in column 3, again has little effect on the results. Dropping the positive-departure-delay requirement but requiring  $R_i^{flight}$  to be less than 1 (which reduces the sample size by 2.5%) serves to reduce the absolute magnitudes of the coefficients without changing their qualitative implications, as seen in column 4. This outcome is expected given the smaller average size of the  $R$  variable.

Table 7 presents regression results using the route-based  $R$  variables. While carrier dummy variables could not be included in the regressions of Table 6 due to collinearity with the tail-number fixed effects, the route-level regressions partly circumvent this problem. To see how, note that, since the  $R$  variables in the table are measured at the route level, the covariates must also be measured at this level. Therefore, each regression covariate is the route-level average of the corresponding variable, with the average specific to either a month or week. In the case of carriers present on the route, this averaging would yield an average of airline dummy variables, equal to the flight shares of the different carriers. But rather than focusing on specific airlines, we instead chose to only distinguish between low-cost carriers (LCCs) and other airlines, on the belief that the different LCC business model requires a separate treatment. Accordingly, the first variable in Table 7 is the LCC flight share on the route, which is a result of the averaging process applied to LCC dummies.

Turning to the  $R_r^{route}$  results in Table 7, column 1 shows coefficients often similar in size and significance to those in column 1 of Table 6. The results show a similar sizable negative effect of a hub origin on the arrival-delay contribution of propagated departure delays. In addition, their contribution rises over the day, with the coefficients strikingly similar in magnitude to those in column 1 of Table 6, while congestion effects are again mixed. In contrast to Table 6, a hub destination has no effect, while greater competition strengthens the contribution of propagated departure delays. The coefficients of the weather variables are insignificant more often than before, but remain negative when significant. The week-based regression in column 2 yields very similar results for the non-weather variables along with weather coefficients that are more frequently significant, showing that weather effects that are lost with a month-level aggregation can be seen at the week level.

Finally, the positive and significant coefficients of the LCC variable in columns 1 and 2 show that propagated departure delays contribute more to arrival delays in the case of low-cost carriers than for other airlines. This finding presumably is tied to one feature of the LCC business model: quick aircraft turnarounds, which make propagated departure delays more likely (as seen in Table 2). The effect is not as large as the effect of a hub origin or an evening departure, but it is still appreciable in size.

Columns 3 and 4 of Table 7 show regressions using the  $\tilde{R}_r^{route}$  variable. Reflecting the reverse pattern seen in Table 2, the hub-origin coefficient is positive in both columns and significant in column 4, instead of being negative. As in the  $R_r^{route}$  regressions,  $\tilde{R}_r^{route}$  is mostly higher later in the day, although the evening-morning differential is much smaller than in columns 1 and 2. Weather effects are mostly insignificant in column 3 but usually positive and significant in column 4, reversing the pattern in Table 6. Even though the LCC effect in Table 2 was very modest, the LCC coefficients in columns 3 and 4 are positive and significant, with magnitudes similar to those in columns 1 and 2.

To appraise these differences relative to the  $R_r^{route}$  regressions, recall that the moderate inbound arrival delay underlying  $\tilde{R}_r^{route}$  is not by itself sufficient to generate a departure delay, with contributions from other random ground-time factors also being required. Since  $\tilde{R}_r^{route}$  then captures a composite of the forces leading to arrival delays, its connections to underlying

determinants cannot be expected to exactly mirror the connections between those determinants and  $R_r^{route}$ , which solely captures the contribution of propagated departure delays. The upshot is that, while the  $\tilde{R}_r^{route}$  regressions are informative, we focus on the  $R_r^{route}$  and  $R_i^{flight}$  regressions in drawing conclusions about the contribution of propagated departure delays to late arrivals.

These regressions yields three important conclusions. First, the contribution of propagated departure delays to arrival delays is lower when the origin is a hub airport rather than a non-hub endpoint. Therefore, airlines appear to run their hubs to limit the extent of propagated departure delays for outbound flights. Second, propagated departure delays contribute more to arrival delays later in the day. Thus, late inbound flights, and the propagated departure delays they generate, appear to be a more significant factor toward the end of the day, when the effects of prior delays have accumulated. Third, the arrival-delay contribution of propagated departure delays is greater in the case of LCCs than for other airlines, reflecting their different business model.

## 6. Conclusion

This paper has offered a simple approach for identifying propagated departure delays and measuring their contribution to arrival delays. Under our approach, a propagated departure delay occurs when the arrival delay of the inbound flight exceeds the subsequent flight’s ground buffer. The size (or frequency) of such propagated delays relative to the size (or frequency) of arrival delays then measures the contribution of propagated delays to late arrivals. This approach differs from earlier attempts to quantify the contribution of delay propagation since it focuses on an individual flight and its immediate predecessor, without attempting to trace the sources of delay propagation back through the entire sequence of prior flights. The paper’s empirical results show that the contribution of propagated departure delays to arrival delays depends on several key determinants.

We hope that other researchers can make use of our approach or extend it to further analyze the effect of airline scheduling decisions on on-time performance. Given the dislike of flight delays by both airlines and passengers, this subject will always be one of ongoing interest.

Table 1: Summary statistics of the delay variables

| Variable                      | Description  | Mean   | Std. Dev. | Min | Max | Obs.      |
|-------------------------------|--|--------|-----------|-----|-----|-----------|
| $D_{a,i}$                     | arrival delay for flight $i - 1$   | -2.235 | 21.688    | -49 | 120 | 4,205,229 |

*Notes.*  $R_{r,month}^{route}$ ,  $R_{r,week}^{route}$ ,  $\tilde{R}_{r,month}^{route}$ , and  $\tilde{R}_{r,week}^{route}$  are computed at airline level. The classification of large, medium, and small airport is based on the ranking obtained from the Department of Transportation (DOT), which reports the total number of enplaned passengers on U.S. and foreign airlines for the main U.S. airports. Large airports are top-10 airports in terms of total number of enplaned passengers in year 2018 (the year of our sample), medium airports are those ranked between positions 11 and 50, small airports are those whose rank is below position 50 or which do not appear in the airport list provide by DOT (for the raking list see <https://www.bts.gov/airport-rankings-2018>, sheet 'Total'). The slot controlled airports are: Reagan National (DCA) airport in Washington, DC and LaGuardia (LGA) and John F. Kennedy (JFK) airports in New York City.

*Notes.* Ordinary least squares estimation with route fixed-effects; constant not reported. The panel identifier is route  $r$  in all columns, whereas temporal dimension of the panel is month in columns (1) and (3) or week in columns (2) and (4). The estimated coefficients marked with \*\*\*, \*\* and \* are statistically significant at, respectively the 1%, 5% and 10% level. The standard errors are clustered by tail number.

Figure 1: Delays

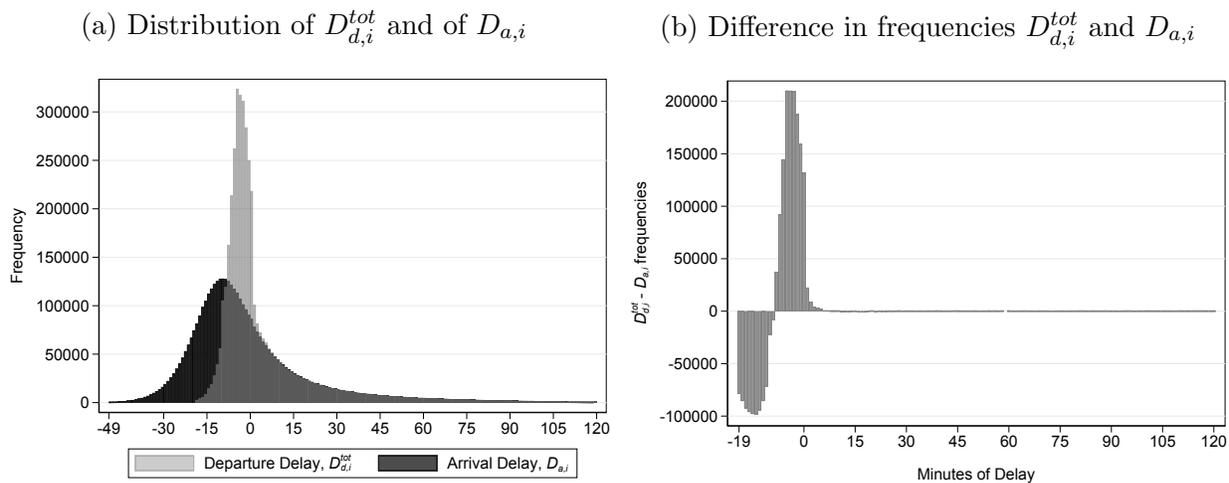

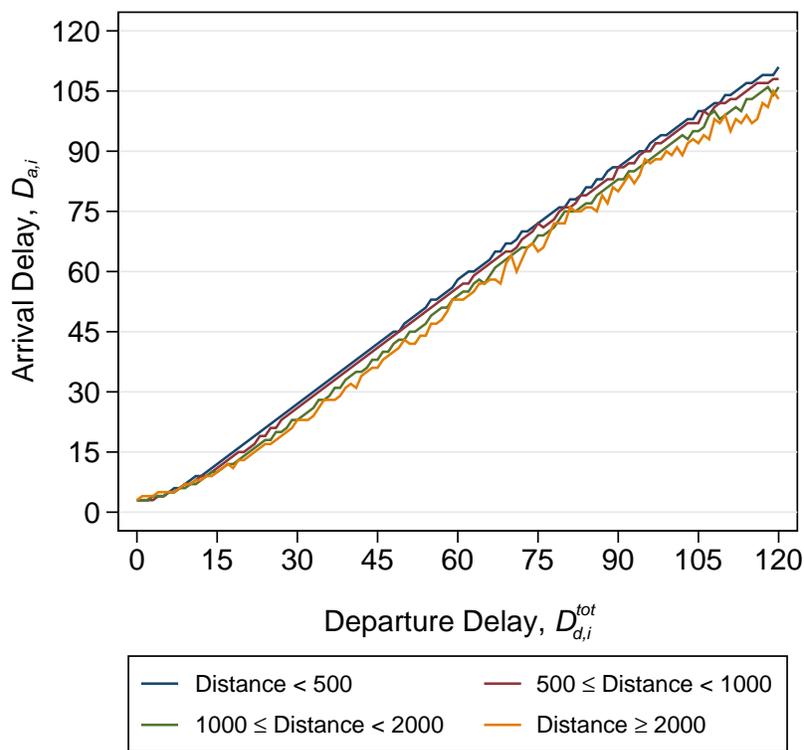

Figure 2: Minutes of delay by route distance (in miles)

# Appendix

Table A1: Description and main statistics of the regressors

| Regressors             | Description  | Mean<br>(Std. Dev.) |
|------------------------|--|---------------------|
| Distance               | Route distance, in 100-mile units  | 7.846<br>(5.610)    |
| Hub origin             | Dummy variable = 1 if airport of origin is a hub of the airline  | 0.382<br>(0.486)    |
| Hub destination        | Dummy variable = 1 if airport of destination is a hub of the airline   | 0.320<br>(0.466)    |
| Congestion origin      | Number of landing and departing domestic flights at the airport of origin in the same hour when the flight is scheduled to depart divided by the number of runways of the airport of origin  | 12.366<br>(7.650)   |
| Congestion destination | Number of landing and departing domestic flights at the airport of destination in the same hour when the flight is scheduled to land divided by the number of runways of the airport of destination                                | 10.640<br>(7.533)   |
| Competitors            | Number of nonstop competitors on the route   | 1.045<br>(1.11)     |
| Morning-Evening        | Set of departure-time dummy variables, <i>Morning</i> (9.00-11.59), <i>Afternoon</i> (12.00-15.59), <i>Late afternoon</i> (16.00-17.59) and <i>Evening</i> (18.00-23.59); the omitted category is <i>Early morning</i> (0.00-8.59) |                     |
| Cloud-Storm            | Set of dummy variables for the weather condition at the airport of origin or destination. <i>Fair</i> is the omitted category  |                     |
| Low temperature orig.  | Dummy variable = 1 if the temperature at the airport of origin is below 32 degrees Fahrenheit  | 0.059<br>(0.236)    |
| Low temperature dest.  | Dummy variable = 1 if the temperature at the airport of destination is below 32 degrees Fahrenheit   | 0.060<br>(0.238)    |
| Low-cost carriers      | Share of flights operated by low-cost carriers (i.e. JetBlue, Frontier Airlines, Allegiant Air, Spirit Airlines and Southwest Airlines). The statistics are for $r, month$   | 0.376<br>(0.449)    |
