# Gender Norms and the Motherhood Employment Gap

## Abstract

Using individual-level data from the European Social Survey, we study the relevance of gender norms in accounting for the motherhood employment gap across 186 European NUTS2 regions (over 29 countries) for the 2002-2016 period. The gender norm variable is taken from a question on whether “men should have more right to a job than women when jobs are scarce” and represents the average extent of disagreement (on a scale 1 to 5) of women belonging to the “grandmothers” cohort. We address the potential endogeneity of our gender norms measure with an index of the degree of reproductive health liberalization when grandmothers were 20 years old. We also account for the endogeneity of motherhood with the level of reproductive health liberalization when mothers were 20 years old. We find a robust positive association between progressive beliefs among the grandmothers’ cohort and mothers’ likelihood to work while having a small child (0 to 5 years old) relative to similar women without children (or fathers). No similar association is found among men (or childless men and women). Our analysis underscores the role of gender norms and maternal employment, suggesting that non-traditional gender norms mediate on the employment gender gap mainly via motherhood.

JEL-Codes: J160, J220.

Keywords: gender norms, motherhood employment gap, instrumenting for motherhood.

The authors would like to thank AER Editor Chinhui Juhn, and three anonymous referees. In addition, the authors thank Purushottam Mohanty for precious research assistance; and Joanna Tyrowitz for bringing the dataset on world reproductive laws by Finlay, Canning, and Po (2012) to our attention. The authors also would like to recognize the comments that helped us improve the paper from participants at IESEG EQM department seminar, the 2019 Gender Economics Workshop in Banco de España, the 1st Workshop in Gender and Economics at the University of Luxembourg, the Women’s Applied Microeconomics Workshop at Columbia University, the first Mannheim-Bonn Labor and Public Economics workshop, Passau University, the 2021 meetings Society of Economics of the Household, and the LEM ADP/MOF Webinar series. Simone Moriconi received financial support by the French National Research Agency for the project “MALYNES” (ANR-18-CE26-000, AAPG 2018), as well as LEM-CNRS 9221 (“appel à projet recurrent”). Both institutions are gratefully acknowledged.

## 1. Introduction

Since the 1990s, adult women's and men's convergence in labor force participation rate and earnings has stalled and even reversed in many OECD countries (Goldin 2014; Blau and Kahn 2006; and England, Levine and Mishel 2020). Recent studies underscore the relevance of motherhood for the persistence of gender inequality in labor market outcomes (Kleven *et al.* 2019). For instance, the earnings loss mothers experience compared to non-mothers (Waldfogel 1997, 1998; Anderson, Binder and Krause 2002, 2003; Gangl and Ziefle 2009; Fernández-Kranz, Lacuesta and Rodríguez-Planas 2013) or fathers (Angelov, Johansson and Lindhal 2016; Kuziemko *et al.* 2018; Kleven, Landais, and Søgaaard 2019a; Kleven *et al.* 2019b) is one of the leading explanations for the gender earnings gap.<sup>1</sup> At the same time, the reduction in maternal labor employment (at both the intensive or extensive margin) is largely responsible for most of the motherhood earnings penalty as shown by Fernández-Kranz, Lacuesta and Rodríguez-Planas (2013) in Spain; Angelov, Johansson and Lindhal (2016) in Sweden; and Kleven *et al.* (2019b) in Scandinavian and Germanic countries, the UK and the US. In the current paper, we analyze the role gender norms play in explaining mothers' decision to work outside the household.<sup>2</sup>

According to Goldin (1995), with industrialization, women's role in society got relegated to being a wife and a mother and working mostly inside the household. Regardless of whether women internalized their assigned gender role, working outside the home was socially stigmatized as gender norms set up "acceptable behavioral boundaries for men and women, congruent with the gender division of labor and male power" (Seguino 2007). As societies evolved and gender norms were relaxed, women were gradually allowed to engage in traditionally male activities including formal education and paid employment in the labor market. While many have studied the role of gender norms on female labor force participation or fertility (Antecol 2000; Fortin 2005; Fernández and Fogli 2009; Blau *et al.* 2013; Bertrand, Kamenica and Pan 2015; Olivetti, Patacchini

---

<sup>1</sup> In a recent study, Kleven, Landais, & Søgaaard (2019a) estimate that having a child is associated with 80 percent of the gender earnings gap in 2013 in Denmark. While the magnitude of this effect varies across countries, others have also underscored the relevance of motherhood in accounting for the persistence of gender inequality in earnings—Angelov, Johansson and Lindhal (2016) for Sweden; Kuziemko *et al.* (2018) for US and UK; Kleven *et al.* (2019), for Sweden, Denmark, the US, the UK, Austria and Germany; and De Quinto, Hospido and Sanz (2020) for Spain.

<sup>2</sup> There is an extent complementary literature on how institutions such as taxes, transfers, parental leave, and childcare policies are related to female labor supply and gender gaps (Olivetti and Petrongolo 2017; Fernández-Kranz and Rodríguez-Planas 2021).

and Zenou 2020; Rodríguez-Planas, Sanz-de-Galdeano and Terskaya 2018; Rodríguez-Planas and Tanaka 2021), few have analyzed whether gender norms mostly affect women's decision to work through motherhood. This is the objective of this paper.

To study the role of gender norms on maternal employment, we exploit geographic (186 European NUTS2 regions over 29 countries), cohort (2 cohorts) and time (2002-2016) variation in gender norms on the employment status of mothers with 0-5 years old children. We measure gender norms with gender role beliefs from individual survey data, in our case from the European Social Survey (2004, 2008, 2010 and 2016). Our measure of non-traditional gender norms is the average extent of disagreement (on a scale 1 to 5) with the statement: "*men should have more right to a job than women when jobs are scarce*", yet we show that results are robust to alternative measures of gender norms. To address the reverse causality problem between contemporaneous peers' gender norms and maternal employment decisions, we focus on women belonging to the grandmothers' cohort to identify gender norms of the mothers. This is based on evidence that gender norms are acquired from women during childhood from their mother or their mothers' peers (Farré and Vella 2013; Rodríguez-Planas, Sanz-de-Galdeano, and Terskaya 2018; Kleven et al. 2019a).

Our baseline model blends the peer effects literature<sup>3</sup> with the motherhood gap literature to identify the effect of non-traditional norms in the grandmothers' cohort on mothers' decision to work relative to childless women. From the peer effects literature, we exploit idiosyncratic variation in average gender norms of the grandmothers' cohort across cohort, NUTS2 region, and survey year. In addition to individual, family, and regional controls, we include NUTS2-region fixed effects to control for endogenous sorting of individuals across regions, and country-and-year fixed effects to control for time-varying unobserved factors that might confound the relationship between grandmothers' non-traditional beliefs and the women's decision to work within a region. From the motherhood gap literature, we estimate the differential effect of grandmothers' gender norms on the employment decision of mothers of young children relative to similar-age childless women. We also show that our results are robust to measuring the motherhood gap by comparing

(2002); Hoxby (2000); Lavy and Schlosser (2011); Lavy, Paserman and Schlosser (2012); Bifulco, Fletcher and Ross (2011); and Olivetti, Patacchini, and Zenou (2020) for papers using peer effects in the field of education. Recently, Rodríguez-Planas and Tanaka (2021) have applied peer effects to explain Japanese women's employment decisions.

mothers' employment decisions to those of fathers. By taking the difference between mothers and childless women (or mothers to fathers), we “wash out” any confounding effects related to female employment as opposed to maternal employment (or to parental employment as opposed to maternal employment). Crucially, to address concerns that our social norms estimates may still be endogenous, we use an index on the degree of liberalization of reproductive health laws in the country when the grandmothers were in their 20s. Furthermore, we explicitly model the endogeneity of the motherhood decision of women in fertile age with the level of exposure the respondent had to reproductive-health liberalization laws when she was in her 20s.

We find a robust and consistent positive association between non-traditional norms in the grandmothers' cohort and mothers' likelihood to work while having a small child (0 to 5 years old) relative to childless women (or to fathers). As no such association is found among fathers of small children relative to childless men (or among childless women relative to childless men), our analysis stresses the relevance of gender norms on maternal employment (but not on paternal employment). Our results are robust to a battery of sensitivity tests.

Our preferred specification finds that a one-standard deviation increase in the predicted average non-traditional gender norm (that is 0.626) is associated with a reduction of 47 percent in the average motherhood employment gap in our sample of 12 percentage points. To put it differently, if mothers from Andalusia (ES23) in Spain, with an average disagreement to traditional gender norms among grandmothers of 2.36 and a motherhood employment gap of 9 percentage points in 2004, were characterized by the mean gender norms in Sweden (e.g. SE21, Småland med öarna), which is equal to 3.77, the statistical model would suggest that the motherhood employment gap in Andalusia would decrease by 12 percentage points, which would fully reverse the observed motherhood employment gap between Småland med öarna and Andalusia (equal to 9 percentage points). Our analysis underscores that non-traditional gender norms mediate on the employment gender gap mainly via motherhood, and hence, to the extent that the motherhood employment gap is largely responsible of the motherhood wage gap, our results suggest the relevance of gender norms for the gender wage gap in Europe.

Our paper contributes to two strands of the literature: the motherhood penalty; and female labor force participation and culture. Within the first strand, we focus on whether gender norms mediate in explaining the gender gap between mothers and non-mothers (but not between fathers

and non-fathers) and between mothers and fathers (but not between childless women and men). To put it differently, an important contribution of our paper is to explore how regional differences in preferences and social constraints are important in explaining the gender gaps observed across regions, but only through motherhood. The few studies that mention the role of gender norms on the motherhood gap have been mostly descriptive and gender norms have not been the focus of their analysis. For example, using data from six countries<sup>4</sup>, Kleven et al. (2019b) find that countries that feature larger child penalties are also characterized by much more gender-conservative views.<sup>5</sup> At the same time, Andresen and Nix (2019) examine child penalties among heterosexual, adopting, and same-sex couples in Norway, with the objective to disentangle the potential sources of the child penalty. The authors find that the child penalties vanish after two years of the first child among same-sex couples but not among heterosexual and adopting couples. After ruling out that child penalties are not driven by costs associated with giving birth, time spent with the child, or relative skill differences across spouses, the authors conclude that child penalties are likely driven by gender norms and gender differences in preferences for childcare.<sup>6</sup> Our analysis combines a battery of approaches that, taken together, suggest that there could be a causal association between gender norms and the motherhood employment gap, even after we account for the endogeneity of the motherhood decision.

We contribute to the second strand of the literature by focusing on the extent to which motherhood is a mediating factor between female employment and culture. In addition to measuring new estimates of the effect of gender norms on women's decision to work, our most relevant contribution to this literature is to show that motherhood is the main channel through which culture/norms impact female labor participation. Relatedly, Boelmann, Raute and Schönnberg (2021) investigate the trade-off between persistence versus adaptation of culture of young mothers who migrated across the East and West Germany border. They document that the motherhood gap in terms of female labor supply is smaller among East German mothers relative to West German mothers. They also find evidence that gender norms are persistent among East

---

<sup>4</sup> The six countries are Austria, Denmark, Germany, the UK, the US, and Sweden.

<sup>5</sup> This paper main objective is to measure child penalties in female and male earnings in different countries using event studies around the birth of the first child. The study finds striking similarities in the qualitative effects of children across countries, but also sharp differences in the magnitude of the effects.

<sup>6</sup> Cortés and Pan (2020) arrive to a similar conclusion for the United States after observing that the motherhood earnings penalties persist for women who are considerably more skilled than their husbands.

German mothers but not West German ones as the latter adjust their behavior to that of their East German peers not only when immersed in East German environment but even after returning to the West. Our work does not discuss the interplay between culture of origin and socialization in the destination. It rather investigates the extent to which culture is responsible of employment gap of mothers, relative to either childless women or fathers. We also complement this other study by using an alternative identification strategy and adding external validity to European regions across 29 countries. Similarly, our work complements the epidemiological literature by using an alternative identification strategy and adding external validity to natives as opposed second-generation immigrants.

The remainder of this paper is organized as follows. Section II discusses the data and our definition of non-traditional gender norms. Section III presents the identification strategy. Section IV present our baseline findings. Section V presents estimates controlling for the endogeneity of motherhood before concluding in Section VI.

## **2. Data and Measuring Non-Traditional Gender Norms**

We use individual-level data from the repeated cross-sectional *European Social Survey* (hereafter ESS), a multi-country survey conducted every other year since 2002, whose main objective is to “assemble data on Europe’s social condition, including the shifting beliefs, values, perceptions and behavior patterns among citizens in different countries.”<sup>7</sup> The ESS ensures that high quality data are collected in each participating country and that they are comparable across participating countries. In addition, ESS data are representative of both the participating countries and the concepts under study. For this purpose, in each participating country, a representative sample of all persons aged 15 and over living in private households are selected using random probability methods.

The survey collects detailed information on respondents’ socio-demographic characteristics, including their age, education level, number and age of children, household income, and NUTS2 region of residence. It also collects information on respondents’ labor market characteristics such as their employment status or previous unemployment experience. The ESS

---

<sup>7</sup> See ESS Survey Specification webpage:  
[https://www.europeansocialsurvey.org/methodology/ess\\_methodology/survey\\_specifications.html](https://www.europeansocialsurvey.org/methodology/ess_methodology/survey_specifications.html)

does not have any information on individuals' wages or earnings. While the ESS gathers detailed information on respondents' parental background, such as parental education, employment status, and occupation when the respondent was 14 years old, it does not link parents to children, so even if two generations were to be surveyed by chance in a particular year, we would not be able to match them. Finally, the data include detailed information on respondents' preferences and beliefs, including beliefs on work and family values.

### ***Measuring Non-Traditional Gender Norms***

To measure beliefs and values that are likely to be relevant for mothers' decision to work, we follow Fortin (2005) and Rodríguez-Planas and Tanaka (2021) and focus on women's belief towards the priority of male employment when jobs are scarce. We decided to focus on beliefs regarding men's versus women's employment priorities instead of housework distribution or women's role within the family because finding that gender norms on men's versus women's employment priorities matter would underscore that it is attitudes and beliefs on gender-based discrimination in the labor market that matter as opposed to gender roles in nurturing the child or responsibilities within the household. We believe that the former is a more relevant and general result. Note that it is not uncommon in this literature to proxy gender norms with: (1) measures of gender equality<sup>8</sup> for outcomes related to math test scores (Nollenberger et al. 2016), reading and science test scores (Rodríguez-Planas and Nollenberger 2018), smoking (Rodríguez-Planas and Sanz-de-Galdeano 2019), and domestic violence (González and Rodríguez-Planas 2020); or (2) work behavior of previous generations (Fernández and Fogli 2006; Fernández 2007). There is also a practical reason that justifies our focus on gender roles in the labor market as opposed to in the household. Attitudes on the former is covered in four waves in the ESS, while attitudes on women's nurturing role is only covered in three waves, and attitudes on gender distribution of childrearing is only covered in one wave of the ESS. In the robustness section, we show results consistent with our main findings as we use alternative measures of gender norms, including the one that stresses the role of attitudes regarding the role of women in the family.

---

<sup>8</sup> Most of the papers cited use the Gender Gap Index from the World Economic Forum, which measures women's economic and political opportunities, education, and wellbeing relative to that of men.

Because beliefs on women’s role in the workplace shape women’s economic decisions, but such decisions also shape beliefs, using contemporaneous beliefs of the economic agents for whom we study their employment choices raises endogeneity concerns that would lead to overestimating the effect of beliefs on mothers’ decision to work. To address such endogeneity issues, we use instead contemporaneous beliefs of the cohort of women in the same age range as the mothers of our economic agents (hereafter the “grandmothers”). In our baseline model, we assume that our gender norms variable (constructed with the beliefs of “grandmothers”) is uncorrelated with contemporaneous labor market decisions of young mothers and affects young mothers’ decision to work only through society’s beliefs towards women working.<sup>9</sup> Later on, we will relax this assumption exploiting arguably exogenous variation in gender norms.

We focus on women belonging to the grandmothers’ cohort to identify gender norms of the mothers because there is evidence that gender norms are acquired from women during childhood from their mother or their mothers’ peers (Thornton, Alwin, and Camburn 1983; Farré and Vella 2013; Rodríguez-Planas, Sanz-de-Galdeano, and Terskaya 2022; Kleven et al. 2019a). It could be argued that measuring grandmothers’ beliefs at a time when their children were young, and not contemporaneously, would best reflect the transmitted gender norms. Yet, this information is not available in the ESS, a repeated cross-sectional dataset that does not match individuals with their parents. Using longitudinal data, several authors have found evidence that gender-role attitudes of mothers and daughters are strongly correlated (Thornton et al. 1983), even after controlling for maternal socio-demographic characteristics (Farré and Vella 2013).<sup>10,11</sup> Also using longitudinal data and directly measuring beliefs, Rodríguez-Planas et al. (2022) find that maternal

---

<sup>9</sup> As explained earlier, as in the ESS data we do not observe the actual mother of our 20- to 40-year-old respondents, our grandmothers are not necessarily the mothers of the young mothers, hence, concerns on whether they are available to provide free childcare assistance is not an issue here. In the empirical analysis, we control for the fertility rate in the residence region, which proxies the local demand for childcare assistance.

<sup>10</sup> Thornton et al. (1983) find strong persistence of gender-role attitudes across mothers and daughters using a longitudinal panel of the attitudes and experiences of a sample of mothers between 1962 and 1980 and the 1980 attitudes of an 18-year-old children in each family. Farré and Vella (2013) examine the relationship between the attitudes expressed in 1979 by female respondents in the NLSY79 aged between 15 and 22 years with those of their children in the CYNLSY79 expressed in the late 1990s and early 2000s when they are the same age (i.e. 15–22 years). They find a strong and statistically significant correlation between the views of the two cohorts, even after controlling for many socio-demographic characteristics of the mothers.

<sup>11</sup> We focus here on studies using direct measures of attitudes on gender roles as opposed to indirect measures, such as the work behavior of previous generations.

gender norms acquired during adolescence through high-school peers have a persistent effect on women's labor market decisions in adulthood (12 years later).<sup>12</sup>

To measure non-traditional gender norms we construct, for each ESS wave, an EU-NUTS2 regional indicator taking the average extent of disagreement (on a 1 to 5 scale with higher values indicating higher disagreement) to the statement “*when jobs are scarce, men should have more right to a job than women*” among grandmothers residing in given EU-NUTS2 region. This indicator is constructed for the following two cohorts of potential “grandmothers”: women 48 to 57 years old and women 58 to 68 years old as women in the same age range as the mothers of our economic agents aged 20 to 29, and 30 to 40, respectively. More precisely, we compute the non-traditional norm indicator as follows:

$$NTN_{crt}^a = \frac{\sum_{j=1}^{M_{crt}^a} Attitudes_{crt}^a}{M_{crt}^a}$$

where  $Attitudes_{crt}^a$  reflects the extent of disagreement on the priority of male employment when jobs are scarce of women in cohort  $a$ , region  $r$  in country  $c$ , and survey wave  $t$ ;  $M_{crt}^a$  is the total number of women in cohort  $a$ , region  $r$  in country  $c$ , and survey wave  $t$ . The superscript  $a$  indicates the age range of women  $j$  in the two cohorts, namely 48 to 57 and 58 to 68 years old. Our non-traditional norm indicator is derived as the cohort/region/wave average disagreement on the priority of male employment when jobs are scarce among potential “grandmothers” and is coded on a 1 to 5 scale such that increasing values denote a more progressive belief towards women.

While the ESS covers years 2002-2018 for 38 countries, we are constrained to use those waves that collect information on beliefs towards the priority of male employment when jobs are scarce. As this question is only available in waves 2004, 2008, 2010, and 2016, we lose five countries (Albania, Kosovo, Luxembourg, Montenegro, and Serbia) because they were not surveyed in any of those four waves. In addition, we lose Israel, Russia, Ukraine, and Turkey

---

<sup>12</sup> Using the National Longitudinal Study of Adolescent Health (Add Health), Rodríguez-Planas et al. (2022) proxy non-traditional gender norms with mothers' beliefs of which skills are more relevant for boys and girls to possess, namely traditional masculine ones (such as thinking for him or herself or working hard) or traditional feminine ones (such as to be well behaved, popular, or helping others), measured when their child was 17 years old and in high school. These authors find that non-traditional gender norms of the mothers of each teenager's high-school peers (excluding his or her own mother) have an impact on the teenager's engagement in risky behaviours when the teenager was in high school but also when he/she was 23 years old. Most importantly in our context, they find that non-traditional gender norms have an impact on women's decision to work when they were 23 years old.

because we lacked regional controls. Our final sample is an unbalanced regional panel covering 29 European countries over the 2004 to 2016 period. In our sample, we have six Continental European countries (Germany, Austria, France, Netherlands, Belgium, and Switzerland), three Anglo-Saxon countries (United Kingdom, Ireland, and Iceland), four Nordic countries (Sweden, Denmark, Finland, and Norway); eleven Central-Eastern countries (Bulgaria, Croatia, Hungary, Czech Republic, Latvia, Lithuania, Romania, Slovakia, Poland, Slovenia, Estonia); and five Mediterranean countries (Italy, Spain, Portugal, Cyprus, and Greece).

Our non-traditional norm indicator is composed of 1,488 cells, covering two cohorts of grandmothers across 186 NUTS2 regions (in 29 countries), over 4 survey waves. Our identification strategy relies on estimating the effects on mothers' decision to work (relative to childless women) of the time varying components of grandmothers' non-traditional norms using the within-NUTS2 region and cohort variation of the country/wave effects, after controlling for: (1) time-invariant regional unobserved heterogeneity (including institutions and policies) with NUTS2 region fixed effects, and (2) time-varying country unobserved heterogeneity (including institutions and policies) with country-and-year fixed effects. Hence, we must show that our identifying variable has enough time variation (and thus grandmothers' gender norms are not only a regional fixed effect) and regional variation (and thus it is not captured by a common year effect). Figures 1 and 2 and Appendix Table A.1 show that our measure of non-traditional gender norms varies both over time, across NUTS2 regions, and across cohorts.

Figure 1 displays the evolution of the non-traditional norms variable over the 2004-2016 period for the two cohorts. We clearly observe variation over time with norms becoming more progressive over the 12-year period. In addition, the prevailing norms for the older cohort are, on average, more conservative than those of the younger one. Figure 2 displays the regional variation of the non-traditional norms variable by plotting the average NUTS2 regional variable over the 2004-2016 period for the younger cohort (on the horizontal axis) against the corresponding value for the older cohort (on the vertical axis). The data points are classified into the following five groups based on geographical location: Continental Europe, Anglo-Saxon countries, Nordic countries, Central-Eastern Europe, and Mediterranean countries. The figure shows considerable dispersion especially among Mediterranean regions, but also among the more moderate regions of Continental and Central-Eastern Europe. In contrast, both Nordic and Anglo-Saxon regions tend to be more progressive and display less variation. As in Figure 1, Figure 2 also shows that the

majority of the data points lie below the 45-degree line, visually confirming that, at the regional level, the younger cohorts of grandmothers are more progressive than the older ones.

Appendix Table A.1 shows the amount of variation that is left in our non-traditional gender norms variable of interest after controlling for region, country-by-year, and cohort fixed effects. The first row in Appendix Table A.1 shows descriptive statistics of our main explanatory variable. The average disagreement on the priority of male employment when jobs are scarce among the grandmothers' sample is 3.713. The standard deviation of this gender norms variable is 63 percent. The second and third rows show residuals after removing birth cohort, year and NUTS2 fixed effects (for row 2) and birth cohort, country-by-year and NUTS2 fixed effects (for row 3). Doing so reduces the standard deviation of the gender norms variable to 27 percent and 18 percent, respectively.

### ***Sample Restrictions***

As our analysis focuses on employment decisions of mothers (fathers) of young children relative to their childless women (men) counterparts, we restrict our analysis to native men and women between 20 and 40 years old as those are the most common childrearing years. We define as native someone who is born in the country of residence, and whose mother is born in the same country. We adopt this definition because our non-traditional gender norm variable is estimated at the cohort/region/wave level using the contemporaneous beliefs of the cohort of grandmothers living in the same NUTS2 region. The presumption here is that gender norms are acquired from women during childhood from their mother or their mothers' peers (Fortin 2005; Farré and Vella 2013; Rodríguez-Planas, Sanz-de-Galdeano, and Terskaya 2018), and hence including immigrants would increase measurement error as it is less likely that they would have been influenced by the older women living in their region of residence.

As we aim at understanding the relevance of non-traditional norms in mothers' decision to work, we further restrict our analysis to mothers (and fathers) whose first child is 0 to 5 years old. As we assume the transmission of the norm takes place through the maternal channel, we also exclude individuals whose mother was dead or absent at the age of 14 years old. In addition to merging ESS individual-level data with our non-traditional gender norms variable at the cohort/NUTS2 region/wave level, we also merge them with other aggregate variables from *Eurostat* (such as the fertility rate, total population, the unemployment rate, the share of the

population with tertiary education) at the NUTS2 by year level (see on-line Data Appendix for details on the precise definition of the main control variables). We exclude regions-by-year cells with ten observations or less. Having more than 10 observations within a cell is not uncommon in papers using a similar methodology in a different context (see, for example, Olivetti, Patacchini and Zenou 2018; Rodríguez-Planas and Tanaka 2021). We also exclude all observations for which there are missing individual or regional controls to have a stable sample across various specifications.

Thus, our final sample includes 30,474 individuals aged 20 to 40 years old —of which 14,476 are females, 4,163 are mothers of young children, and 3,103 are fathers of young children— living in 29 countries during the period 2004-2016. In each regional-by-year cell there are on average 54 individuals (25 women), ranging between 11 and 456 individuals (the median being 36 individuals).

### ***Descriptive Statistics***

Appendix Table A.2 presents descriptive statistics for our sample of mothers and childless women (Panel A), and fathers and childless men (Panel B). On average, 54 percent of mothers in our sample are employed, a considerably lower share than childless women (two thirds work), childless men (70 percent work) and fathers (91 percent work). On average, mothers (fathers) in our sample are three (or four) years older and more likely to be married than childless women (childless men). While both parents are less likely to have secondary education than childless adults, they are more likely to have tertiary education than them. In contrast, mothers have longer past unemployment experiences than childless women, but the opposite is true for fathers and childless men. On average, non-traditional gender norms of mothers are 14.7 percentage points (or 3.6 percent) more conservative than childless women; whereas fathers' non-traditional norms are 10 percentage points (or 2.6 percent) more progressive than that of childless men. In the robustness section, we show that the association between grandmothers' cohort non-traditional norms and the first-child employment gap holds even after controlling for the respondent's own gender norms.

Figure 3 uses the raw data to plot the relationship between the first-child employment gaps (the motherhood gap) and our non-traditional gender norms based on the beliefs of the grandmothers' cohort. Importantly, it shows a smaller motherhood gap in NUTS2 regions with

less traditional views. The figure plots on the y-axis the average differences in employment between mothers and childless women (panel A) and between mothers and fathers (panel B) against the average extent of disagreement with the statement above among the “grandmothers” in 184 NUTS2 regions (or non-traditional gender norm, NTN), on the x-axis. It shows that NUTS2 regions with smaller negative employment differences (that is, smaller motherhood penalties) are also those with less traditional views (that is, higher NTN). Correlations are sizeable and always statistically significant at conventional levels. While not necessarily causal, this evidence underscores the association between gender norms and maternal employment.

### 3. Estimation Strategy

In this section, we first describe the identification strategy of our baseline model, which exploits variation across birth-cohorts and survey year within NUTS2 regions to obtain an estimate of non-traditional gender norms on the decision to work of young mothers relative to childless women; and we investigate the validity of our identification strategy. To address concerns that our social norms estimates may be endogenous, we exploit variation in reproductive health laws at the country level when the grandmothers were in their 20s. Lastly, we exploit variation in reproductive health laws at the country level when the mothers were in their 20s to account for the fact that the decision to have a child is endogenous.

#### 3.1 Baseline Model: The Motherhood Gap Within Estimate

##### *Identification Strategy*

Pooling mothers and young women in our sample, we estimate the following motherhood gap model within cohort, region and country-by-year fixed effects model:

$$Y_{icrt}^{a-28} = \alpha_0 + \alpha_1 NTN_{crt}^a + \alpha_2 Small\ Child_{icrt}^{a-28} + \alpha_3 (NTN_{crt}^a * Small\ Child_{icrt}^{a-28}) + X_{icrt}^{a-28'} \gamma + Z'_{crt} \delta + \varphi_r + \phi_{ct} + \varepsilon_{icrt}^{a-28} \quad (1)$$

where  $Y_{icrt}^{a-28}$  is equal 1 if individual  $i$  from birth cohort  $(a-28)$ , living in NUTS2 region  $r$  of country  $c$ , is working in survey year  $t$ , zero if the individual is not working.  $NTN_{crt}^a$  is the average disagreement on the priority of male employment when jobs are scarce of women in cohort  $a$ ,

region  $r$  of country  $c$ , and survey year  $t$ .  $Small\ Child_{icrt}^{a-28}$  is equal 1 if individual  $i$  from birth cohort  $(a-28)$ , living in NUTS2 region  $r$  of country  $c$ , has a child 0 to 5 years old in survey year  $t$ , zero if she is childless.  $X_{icrt}^{a-28'}$  is a vector of individual-specific covariates measured at survey year  $t$ , namely age, age squared, two education dummies<sup>13</sup>, two dummies for marital status<sup>14</sup>, a dummy for being in a low-income household<sup>15</sup>, one dummy for having experienced unemployment in the last five years, and two dummies for parental employment (one for the father and one for the mother) when the respondent was 14 years old.  $Z'_{crt}$  is a set of regional/year covariates measured contemporaneously such as the unemployment rate, the fertility rate, the total population, the share of tertiary educated individuals in the population.<sup>16</sup> We also include NUTS2 region fixed effects ( $\phi_r$ ), as well as country-by-year fixed effects ( $\phi_{ct}$ ).<sup>17</sup> Standard errors are clustered at the NUTS2 regional level.

Our estimate of interest,  $\hat{\alpha}_3$ , captures the association between the change of non-traditional norms of the grandmothers' cohorts and the change of mothers' decision to work relative to childless women, also known as the motherhood employment gap, within the NUTS2 region  $r$ , and conditional on the included covariates. A positive and statistically significant  $\hat{\alpha}_3$  would indicate that an increase in the progressiveness of grandmothers living in the NUTS2 region  $r$  is associated with an increase in the probability of local mothers to work. Hence, a positive and statistically significant  $\hat{\alpha}_3$  would indicate that more progressive gender norms among grandmothers' cohort is associated with a smaller motherhood employment gap. In addition, to control for a rich set of individual characteristics known to be associated with employment (including individuals' human capital investment, prior unemployment history, household income

---

<sup>13</sup> Dummies for secondary and tertiary education, with primary education as the reference group.

<sup>14</sup> Dummies for never married and no longer married, with currently married as the reference group.

<sup>15</sup> Dummy for being in a household with an income below 15,000 euros per year (households with income higher than 15,000 euros per year are the reference group).

<sup>16</sup> In addition to these variables, we also considered many other controls such as the female-to-male differences in the unemployment rate and in the share of tertiary educated individuals, the median age in the region, GDP per capita, and our own computation of female-to-male Bartik wage ratios based on Eurostat SES, EU-SILC, or LFS Data (see on-line Data Appendix for details). We do not include these indicators in the baseline set of controls as they do not turn out as statistically significant, and/or entail a significant loss of NUTS2 regions. We also considered the number of births, as an alternative to the fertility rate (as the two are strongly correlated). All these results are available to the authors upon request.

<sup>17</sup> Note that the inclusion of a dummy for the younger cohort of respondents to capture time invariant average differences between the two cohorts is unnecessary as the presence of country-by-year fixed effects and linear and quadratic age makes the former dummy redundant. In Table 4 Panel M, we present a robustness check that includes such cohort dummy.

and parental background), as well as a rich set of time-varying regional characteristics that may influence the outcome of interest, model (1) is able to control for time-varying unobserved heterogeneity (including institutions and policies) that affects employment decisions at the NUTS2 regional level of both mothers and childless women in the same way. At the same time, the country/year fixed effects control for cross-country differences in employment levels and business cycle that could potentially affect female employment generally.

We also estimate model (1) using fathers of small children and childless men. Importantly, finding no evidence of association between the gender norms in the grandmothers' cohort and the employment gap between fathers and childless men would suggest that beliefs towards the appropriateness of female employment among the grandmothers' cohort mediates *only* via motherhood, not fatherhood, and hence are not due to systematic differences between parents and non-parents within a region.

Identification comes from variation in grandmothers' gender norms across birth-cohorts over time within a NUTS2 region. This variation can be considered as quasi-random if the following two conditions are met. First, being in one cohort or another is beyond one's control as one does not choose the year (cohort) one is born into. Second, the difference in unobserved heterogeneity across cohorts within a NUTS2 region for a given survey year is not driven by unobserved factors that may also influence a mother's decision to work in a wage and salary job, conditional on the set of individual controls. It is important to note that we include a dummy equal to one if the mother of the respondent (i.e. the actual grandmother of the child) was working when the respondent was aged 14y.o. The inclusion of this variable guarantees that the estimated effects of  $NTN_{crt}^a$  on employment of the mother in equation (1), is not driven by the actual labor supply of the grandmother.

### ***Validity of the Identification Strategy***

In Table 1, we present balancing tests for our non-traditional gender norms variable separately for mothers, childless women, fathers, and childless men. They show the coefficient on the non-traditional norms of the grandmothers' cohort variable in a regression of individuals' socio-demographic characteristics or regional characteristics on the grandmothers' cohort non-traditional gender norms variable, a cohort dummy, NUTS2 regions fixed effects, and country/wave fixed effects. Focusing on our subgroup of interest, mothers, column 1 in Table 1

reveals that one of fourteen coefficients are statistically significantly different from zero at the 10% level, and none are statistically significantly different at the 5% level. In both cases, this is less than what we would expect by chance. These tests reveal that controlling for birth-cohort, NUTS2 region and country/wave fixed effects is likely to be sufficient to isolate variation in our grandmothers' gender norms variable that is not systematically related to mothers' socio-demographic composition within NUTS2 regions. Nonetheless, we will add many individual and time-varying regional controls. The balancing tests show that there are only two of fourteen systematic relationships (statistically significant at the 10% level) between our grandmothers' gender norms variable and the socio-demographic composition of childless young women within NUTS2 regions. The balancing tests for fathers or young childless men reveal that only one of fourteen coefficients significantly different from zero for fathers and none for childless men.

Despite the individual and regional controls included in model (1) and the fact that our gender norms variable is measured using the grandmothers' cohort (as opposed to the cohort of the individual for which we are studying employment decisions), concern that  $E(NTN_{crt}^a \varepsilon_{icrt}^{a-28}) \neq 0$  may still remain. One concern is that there is reverse causality as preferences of the grandmothers' cohort change when observing the employment and motherhood decisions of their daughters' or their daughters' friends/peers. Alternatively, endogeneity of our main explanatory variable may be driven by omitted region-level or individual factors that may be associated with both the non-traditional gender norms of the grandmothers' cohort and the maternal employment of their daughters' cohort, for reasons unrelated to gender norms. To address such endogeneity concern, we take the approach discussed in the Section 3.2.

### **3.2 An IV approach: Exposure to Health Liberalization Laws in the presence of Exogenous Demographic Shocks**

To address the potential endogeneity of the grandmothers' cohort non-traditional norms variable,  $NTN_{crt}^a$ , we exploit variation coming from a combination of institutional reforms in countries' reproductive health laws and exogenous regional demographic shocks in the Post-WWI period. In practice, we construct an instrument that features the degree of health liberalization faced by the grandmothers' cohort at the age of 20 years old. Regional demographic shocks associated with so called "Baby Boom" and "Baby Bust" determine the age distribution of grandmothers at time  $t$ .

The rationale for exploiting such combined cross-country and cross-regional (within country) variation lies in Goldin and Katz (2002)’s argument that reproductive-health liberalization laws (such as the contraceptive pill) raised women’s awareness. We argued this may have favoured the development of less traditional gender norms in different ways in different regions, depending on the relative size of cohorts that were directly exposed to the liberalization (or not). This variation is as good as exogenous as it is unlikely that each individual grandmother, *per se*, influenced the legalization of the pill or the abortion in her country. Our cohorts of grandmothers were aged 20 years old between 1956 and 1988. Crucially, regularization laws that took place during this “exposure window” are random with respect to the counterfactual employment decision to work of younger women (born after these liberalizations took place) in the period 2004 to 2016 and living in regions with more or less progressive gender norms.

Finlay, Canning, and Po (2012)<sup>18</sup> developed an original dataset on Reproductive Health Laws Around the World for the period 1960-2009, which we have updated to describe the environment our grandmothers were exposed to during the period 1956 to 2016.<sup>19</sup> We call  $Liberalization_{ct}$  the degree of liberalization of contraceptive pill and abortion laws<sup>20</sup> in country  $c$  at time  $t$  available for our sample of countries. We assign to each grandmother  $j$ , (i.e. to each woman between 48-68 years old) the degree of liberalization she was exposed to in her country  $c$  at the age of 20 (that is, at  $t - age + 20$ ). This is the degree of liberalization observed in each country between 1956 and 1988. After that, we construct an index of average grandmothers’ exposure to reproductive health laws at the region  $r$  by cohort level  $a$  in country  $c$  at survey wave  $t$ :

$$GrandExposure20_{crt}^a = \frac{\sum_{j=1}^{M_{crt}^a} Liberalization_{cj(t-age+20)}}{M_{crt}^a}$$

---

<sup>18</sup> The working paper is available here: [https://cdn1.sph.harvard.edu/wp-content/uploads/sites/1288/2013/10/PGDA\\_WP\\_96.pdf](https://cdn1.sph.harvard.edu/wp-content/uploads/sites/1288/2013/10/PGDA_WP_96.pdf).

<sup>19</sup> We made three major updates of data from Finlay, Canning, and Po (2012). First, we extended the degree of liberalization observed in 1960 back to 1956, after verifying that no country had introduced relevant reforms according to the taxonomy proposed by Finlay, Canning, and Po (2012). Second, we accounted for abortion liberalizations during the 1970s in former GDR/DDR (to which German grandmothers were exposed to), and former Yugoslavia (to which Croatian and Slovenian grandmothers were exposed to). Third, we accounted for further contraceptive pill liberalizations during 2009-2016 in Portugal, Slovenia, Slovakia, and Czech Republic.

<sup>20</sup> A third dimension of reproductive health legislation is available in the data, which concerns the legalization and commercialization of Intrauterine devices (IUD). We decide not to consider it as it proves largely irrelevant in the present analysis. Further details are available to the authors upon request.

where  $M_{crt}^a$  is the total number of grandmothers from cohort  $a=48/57, 58/68$  in region  $r$  of country  $c$  in survey wave  $t$ .  $GrandExposure20_{crt}^a$ , constructed in this way, measures the degree of liberalization of reproductive health laws (either contraceptive pill or abortion) grandmothers from cohort  $a$  resident in region  $r$  of country  $c$  at time  $t$  were exposed to when they were 20 years old (i.e. at time  $t-age+20$ ). This indicator ranges between zero (indicating grandmothers were exposed to a full prohibition of contraceptive pill and abortion) and one (indicating grandmothers were exposed to full liberalization of abortion, as well as a full commercialization of contraceptive pill).

$GrandExposure20_{crt}^a$  exhibits variation across countries, across regions (within the same country), overtime, and between cohorts. Figure 4 and Appendix Table A-3 displays the variation of  $GrandExposure20_{crt}^a$  for each country in the sample. Each dot in Figure 4 represents the average degree of exposure to health liberalization laws for a given cohort of grandmothers in region  $r$ . Red squares refer to the ‘old’ cohort (i.e.  $a=58-68$  years old), while blue triangles refer to the ‘young’ cohort of grandmothers (i.e.  $a=48-57$  years old). The  $GrandExposure20_{crt}^a$  indicator takes values that are generally larger for the younger cohort of grandmothers relative to the older cohort, and monotonically increasing over the 2004-2016 period. This is due to the fact that liberalization effect of reproductive-health liberalization reforms in most countries accumulate overtime. Figure 4 shows some important exceptions in countries from Central and Eastern Europe (CEE) such as Bulgaria, Hungary, Romania, and the Baltic countries, which experienced temporary reversals in the degree of reproductive-health liberalizations during the 1970s.<sup>21</sup>

One potential concern with  $GrandExposure20_{crt}^a$  is the presence of omitted country-level factors that may relate to country-specific increasing trajectories in economic and social development, educational attainments or income of the population. These factors may undermine the validity of the instrument if they both increase the probability of non-traditional laws that determine the variation of  $Liberalization_{cj(t-age+20)}$  and the progressiveness of the gender norms of women, which are measured by the  $NTN_{crt}^a$  indicator 28 years later. These omitted factors may invalidate our identification strategy, if they also have a direct effect on the

---

<sup>21</sup> In Bulgaria abortion was prohibited in the mid-70s and was gradually re-introduced in the following years. In Hungary, abortion requests were initially legal, but prohibited in 1973 to be legalized again in 1993. In Romania, both the use of contraceptive pill and abortion was restrained in the 1960s before being reintroduced again in the late 1980s. Finally, in the Baltic countries the contraceptive pill was also legal back to 1956, and then prohibited between 1974 and 1982. See Finlay, Canning, and Po (2012) for details. These patterns can be seen in Figure A.2 in the Appendix, which displays the sample variation of the original variation in Finlay, Canning, and Po (2012) by country.

employment probability of mothers that we observe at time  $t$ . To investigate the existence of such trajectory, in Figure 5 we plot the change of the degree of liberalization between 1960 and 1980, against the ten years lagged change in female participation rates (i.e. for the period 1950-1980). This is the original proxy of gender norms proposed by Fernandez and Fogli (2009). The figure does not suggest any positive correlation between past changes in the country-specific gender norm and changes in the degree of health liberalization. No association emerges even in Table 2, which presents results from a more formal pre-trend analysis where we use a ten years differences estimator and regress the change in liberalization occurred over a 10 years' period (say between 1980 and 1990) on the corresponding ten years lagged change in female labor force participation in a country (i.e. between 1970 and 1980). There is no evidence any positive association, even when we include time dummies to the regression. If any, there is a negative association, which is never statistically significant. Overall, results in Figure 5 and Table 2 reassure us against the existence of omitted country-specific factors that may determine a spurious correlation between changes in the degree of liberalization and changes in the non-traditional gender norm.

Besides, a crucial source of variation in  $GrandExposure20_{ct}^a$  is triggered by cross-regional heterogeneity of demographic developments within a country. Indeed, the dispersion of red squares and blue triangles in Figure 4 signals considerable variation across cohorts, between NUTS2 regions in each country, and overtime. Importantly for our identification strategy, these sources of variation are mostly related to exogenous demographic shocks. Figures 5 and 6 are useful to describe this variation. The former figure plots the average size ratio between the two cohorts of grandmothers in each country in our sample period:  $M_{ct}^{48-} / M_{ct}^{58-68}$ . It shows that for two thirds of the countries in our sample, the younger cohort is larger in size than the older one (i.e. a ratio larger than one; see horizontal red line in Figure 6). In most countries, the relative size of the younger cohort is larger in the earlier years of our sample period.<sup>22</sup> This is partly driven by the 'baby boom', which in most countries occurred in the aftermath of WWII. Women born during the 'baby boom' are initially concentrated in the younger cohort of grandmothers. Yet, with time, they transition to the older cohorts. Hence, on average, declining ratios in countries characterized by an initially high ratio (see e.g. countries from Central Eastern Europe in Figure 6) reflect the baby bust that followed the baby boom (see e.g. Jones & Schoonbrodt, 2016). Figure 7 plots

---

<sup>22</sup> Exceptions are countries where the baby boom was weaker or absent (such as Germany, Switzerland, the Netherlands, Italy, Greece, and Spain) or countries where it started earlier (such as the UK).

regional level variation of young-cohort size ratios by country group. Over the sample period, we observe somehow different cross regional patterns in countries belonging to different geographical groups in Europe. This is consistent with evidence from the demography literature that points out highly heterogeneous patterns of regional convergence or divergence in the aging process e.g. in Continental Europe versus Mediterranean or Anglo-Saxon countries (see Kashnitsky et al. 2017, for details).

**Auxiliary Regression.** Hence, our assumption is that the degree of exposure to reproductive health liberalization laws in the country when the grandmother was 20 years old is correlated with her beliefs on women's role in the workplace (namely, the gender norm transmitted to the next generation), but it only impacts the employment decisions of the next generation of mothers through such beliefs, once we control for time-varying controls, and fixed effects.

This conjecture leads us to estimate the following auxiliary regression stage at the region-cohort-year level:

$$NTN_{crt}^a = \gamma_0 + \gamma_1 GrandExposure20_{crt}^a + Z'_{crt}\delta + \varphi_r + \phi_{ct} + \varepsilon_{crt}^a, \quad (2)$$

where all the variables and vectors have been previously defined. The coefficient  $\gamma_1$  in equation (2) describes the persistent effect of exposure of grandmothers belonging to cohort  $a$  in region  $r$  to health liberalization laws in their country  $c$  on their gender views. Estimation of equation (2) exploits difference-in-differences variation due to the specific timing of health liberalization laws implemented in country  $c$ , in the presence of the exogenous demographic patterns that determine the composition of cohorts  $a=48-57, 58-68$  in region  $r$  at time  $t$  as described above. Such difference-in-differences identification strategy “washes out” confounding effects that would correlate positively with the daughter's female labor force participation broadly for reasons unrelated to more liberal reproductive law changes such as women's increased exposure to technology, or the secularization process in place in modern societies. We can look at an example to better convey the intuition of this.

Take the case of women born in France in 1955. During the 2004 to 2012 period, we observe them in the younger cohort of grandmothers, exposed to the pill and abortion liberalization that took place in France in 1975, a reform that did not affect the correspondingly older cohort of

French grandmothers (as these were old enough by then). During the 2014 to 2018 period, the 1955 French cohort of grandmothers becomes the older cohort instead. In this case, it is the older cohort that is treated by the 1975 French reform; and the younger cohort, which is not treated as they were too young in 1975, is the comparison group. Note, that any omitted cultural processes (such as exposure to technological progress and the digital revolution or the secularization of society) that would make the gender views of more recent cohorts of women in our dataset less traditional would be orthogonal to our treatment in recent survey waves as the younger cohort of grandmothers constitutes the control group.<sup>23</sup> This example shows how exposure to abortion or pill liberalization reforms shapes individual views of grandmothers living in region  $r$  at time  $t$  in equation (2). Depending on the exact timing of the law, and the survey year, one cohort would include ‘treated’ grandmothers, the other cohort being the control group. The specific demographic patterns followed by each region  $r$  determines the relative size of the two cohorts over time. Such difference-in-differences variation excludes any omitted factors correlated with the age of the grandmother that may also affect her gender views (and hence her daughter’s employment decision) for reasons unrelated to reproductive health laws.

In Panel A, Table 3, we report results from three different specifications of auxiliary regression (2). In column 1, we compute  $GrandExposure20_{crt}^a$  using both abortion and pill liberalization laws; in column 2, we consider only abortion liberalization laws; and in column 3, we enter pill and abortion liberalization laws separately in equation (2). Estimates evidence a positive coefficient  $\hat{\gamma}_1$ , statistically significant at the 1% level in columns 1 and 2. Column 3 reveals that abortion legalization is more precisely estimated than pill liberalization. The coefficient  $\hat{\gamma}_1$  in column 1 indicates that one standard deviation increase in exposure to a liberal environment (in terms of reproductive health) is associated with grandmothers having more progressive views regarding the role of women in the labor market by of 0.131 ( $= 0.19 \times 0.691$ ) points. This magnitude is better assessed considering that one standard deviation increase in  $GrandExposure20_{crt}^a$  consists of the max-min difference in grandmothers’ exposure for a country like Belgium, both in terms of the actual reforms implemented (Figure A-2) and its young-cohort size ratio during sample period (Figure A-3). Our estimates suggest such an increase in

---

<sup>23</sup> In Appendix Table A-6, we provide further evidence in favor of this argument. We show that our results are broadly confirmed as we gradually restrict our sample to more recent years so as to have only the older cohort of grandmothers exposed to the reform. Economic significance vanishes only as we restrict analysis to years 2014-2018, as in this way we lose the 86% of our initial sample. The positive coefficient of the interaction term is however preserved in this case too.

exposure at age 20 makes grandmothers more progressive by about the 17% of a standard deviation of the NTN variable. This is non-negligible considering that grandmothers preferences are measured 30 to 40 years after their exposure.

These results suggest that greater exposure to reproductive health laws when grandmothers were in their 20s is associated with more progressive gender views among the grandmothers' cohorts about three to four decades later. This is evidence consistent with the “impressionable years” hypothesis (Newcomb et al., 1967. See Bietenbeck et al. 2023 for a recent study on impression effects on individual attitudes), the idea being that such laws raise persistently women's awareness and foster the development of more progressive gender norms. In Appendix Table A-4, we show that these findings are confirmed as we use the share of women disagreeing (instead of the average extent of disagreement) with the statement: “*men should have more right to a job than women when jobs are scarce*”, or a different definitions of the non-traditional gender norms focusing on grandmothers' views regarding women's nurturing role, as well as gender distribution of childrearing.

**Estimates that Correct for Endogenous Gender Norms.** Using the auxiliary regression, we estimate a predicted norm  $\widehat{NTN}_{crt}^a$ , which we use as the main regressor in the following model:

$$Y_{icrt}^{a-28} = \alpha_0 + \alpha_1 \widehat{NTN}_{crt}^a + \alpha_2 Small\ Child_{icrt}^{a-28} + \alpha_3 (\widehat{NTN}_{crt}^a * Small\ Child_{icrt}^{a-28}) + X_{icrt}^{a-28'} \gamma + Z'_{crt} \delta + \lambda_a + \varphi_r + \phi_{ct} + \varepsilon_{icrt}^{a-28} \quad (3)$$

Equation (3) features the standard properties of an OLS estimator as equation (1). However, while a major concern in OLS estimates in equation (1) is related to the endogeneity of NTN, such concerns are greatly mitigated in equation (3).<sup>24</sup> Appendix Table A.5 shows descriptive statistics of  $\widehat{NTN}_{crt}^a$  and compares it with the observed  $NTN_{crt}^a$ . The appendix table shows that both observed and predicted norms have very similar distributions, means and standard deviations.

In equation (3) above, time variation within the same region is guaranteed by the change in the age structure of the population of grandmothers between 2004 and 2016 (that is, the exact age composition of grandmothers in the group  $M_{crt}^a$ ). This allows the inclusion of region fixed

---

<sup>24</sup> Our approach can be considered akin to an IV approach despite of the fact that it is not equivalent to estimating equation (1) by 2SLS. In fact the interaction  $\widehat{NTN}_{crt}^a * Small\ Child_{icrt}^{a-28}$  in equation (3) is not equivalent to the linear projection of  $NTN_{crt}^a * Small\ Child_{icrt}^{a-28}$ . In Table 4 we verify our results are confirmed in a 2SLS model where we instrument  $NTN_{crt}^a * Small\ Child_{icrt}^{a-28}$  in equation (1) by  $\widehat{NTN}_{crt}^a * Small\ Child_{icrt}^{a-28}$ .

effects. In this case,  $\hat{\alpha}_1$  and  $\hat{\alpha}_3$  are identified by the variation in the age composition of grandmothers within each region over time.  $\hat{\alpha}_3$  is our main coefficient of interest. It measures the effect of the (predicted) gender norm in the region on the employment outcome of mothers, relative to childless women. We argue that the difference-in-differences approach described above features a source of exogenous variation in gender norms related to the exposure to reproductive health liberalization laws in the country when the grandmother was 20 years old. This guarantees the predicted norm only impacts the employment decisions of the next generation of mothers through their own beliefs (namely, the gender norm transmitted from the previous generation), once we control for time-varying individual controls (included in vector  $X_{icrt}^{a-28}$ ), regional controls (included in vector  $Z'_{crt}$ ), region fixed effects  $\varphi_r$ , and country-by-year fixed effects  $\phi_{ct}$ . Standard errors are clustered at the region level and bootstrapped with 200 replications, since our main regressor is a generated variable.

We address concerns that the exclusion restriction is violated if the liberalizations of health laws have indirect effects on fertility by excluding in our preferred specification young women who were born before such legalizations took place. While it could be argued that the exclusion restriction could still be threatened if the liberalizations of the health laws lead to selection into marriage or divorce or changes in household bargaining, we argue that to the extent that such behavioral changes reflect changes in gender norms widely defined, our causal claims hold. Nonetheless, to the extent that potential behavioral changes resulting from the reproductive health laws were to be considered alternative channels to gender norms, claims of causality would be too strong, and the analysis presented below would instead make a strong and quite convincing argument that gender norms are important to understand cross-country differences in female employment in the EU.

In the robustness section, we will also present a placebo test where we assign to each women a predicted norm  $\widehat{NTN}_{crt}^a$  that has been randomly drawn from a normal distribution having the same mean and the same standard deviation as our predicted norm  $\widehat{NTN}_{crt}^a$ . Finding no evidence of association between this random measure of gender norm in the grandmothers' cohort and the employment gap between mothers and childless women would suggest that our findings are not the results of other confounding effects.

#### 4. Main Findings

Column 1 in Panel A in Table 4 shows the baseline model: the motherhood gap within, region, and country-by-year fixed effects. Columns 2 and 3 present results from estimating model (3) in which the potentially endogenous non-traditional gender norms variable has been replaced with its predicted measure,  $\widehat{NTN}_{crt}^a$ , estimated from the first-stage equation (2). The difference in the specification used in columns 2 and 3 is that the former exploits variation in exposure to both the pill and the abortion liberalization laws, whereas the latter only exploits variation in exposure to abortion liberalization laws. In all three specifications,  $\hat{\alpha}_3$  is positive and statistically significant at the 5% level suggesting that living in regions with more progressive gender norms among the grandmothers' cohort is associated with a higher likelihood of maternal employment relative to childless women relative to the motherhood gap in regions with more traditional gender norms among the grandmothers' cohort. Moving from the baseline model (column 1) to the ones that address endogeneity (columns 2 and 3) increases the size of  $\hat{\alpha}_3$  from 5.3 percentage points to 5.5 and 5.7 percentage points. Columns 4 and 5 in Panel A in Table 4 address concerns that the exclusion restriction may be violated if our respondents were born before the legalization of the reproductive health laws. To do so, we re-estimate the model used in column 2 but only including in the sample respondents who were born after such legalizations took place (abortion only in Column [4], and both abortion and pill in Column [5]). Moving from column 2 to column 4 or column 3 to column 5 shows a stronger and more precise relationship between predicted gender norms among the grandmothers' cohort and the motherhood employment gap. Column 6 presents our preferred specification, as we re-estimate the specification in column 4, excluding respondents from countries in which grandmothers were not affected by any changes in the reproductive health laws when they were in their 20s. Doing so has a minimal impact on the size, the sign, and the precision of  $\hat{\alpha}_3$ . This reassures us that our results are not driven by countries that do not display any variation in the instrument.

Estimates in column 6 in Panel A in Table 4 show that non-traditional norms of the grandmothers' cohort are directly related to maternal employment. More specifically, we find that an increase in the predicted average disagreement on the priority of male employment when jobs are scarce of women in the grandmothers' cohort by one standard deviation is associated with an

increase in the likelihood that mothers with small children work of 5.6 percentage points<sup>25</sup>, the equivalent of a reduction of 46.7 percent in the average motherhood employment gap in our sample of 12 percentage points.<sup>26</sup> To put it differently, if mothers from Andalusia (ES23) in Spain, with an average disagreement to traditional gender norms among grandmothers of 2.36 and a motherhood employment gap of 9 percentage points in 2004, were characterized by the mean gender norms in Sweden (e.g. SE21, Småland med öarna), which is equal to 3.77, the statistical model would suggest that the motherhood employment gap in Andalusia would decrease by 12 percentage points, which would fully reverse the observed motherhood employment gap between Småland med öarna and Andalusia (equal to 9 percentage points).<sup>27</sup>

Our preferred specification (in column 6, Panel A in Table 4) also reveals a motherhood employment gap of 71 percent (or 46.2 percentage points) of the average employment among childless women in our sample (equal to 65.5 percent as shown in Table A-2). In addition, we also find that gender norms of the grandmothers' cohort are associated with an increase in the employment rate of childless women. This is consistent with results from well-known studies in the cultural economics literature that did not consider explicitly the motherhood channel and find an association between less traditional gender norms and female employment more generally (see, for example, Fernández and Fogli, 2009). Interestingly enough, the effect of the norm on childless women is not robust to accounting for the endogeneity of motherhood as we discuss in Section V.

### ***Results using Fathers and Childless Men***

Panel B in Table 4 replicates the above exercise but using fathers of young children and childless men. Focusing first on the differential impact of gender norms of the grandmothers' cohort on the fatherhood employment gap, we observe that there is no effect as  $\hat{\alpha}_3$  is mostly zero. Evidence of no association between the gender norms in the grandmothers' cohort and the employment gap between fathers and childless men suggests that beliefs towards the appropriateness of female employment among the grandmothers' cohort mediates only via motherhood, not fatherhood, and

---

<sup>25</sup> This is calculated as:  $\hat{\alpha}_3 * \widehat{NTN}_{StDev} = 0.087 * 0.644 = 0.056$

<sup>26</sup> This is calculated as  $\frac{\hat{\alpha}_3 * \widehat{NTN}_{StDev}}{Motherhood\_Gap_{Mean}} = \frac{0.087 * 0.644}{-0.116} = \frac{0.056}{-0.116} = -0.467$

<sup>27</sup>  $(Motherhood\_Gap(ES23) - Motherhood\_Gap(SE21)) * \hat{\alpha}_3 = (3.77 - 2.36) * 0.087 = 1.41 * 0.087 = 0.123$ .

hence our findings on the motherhood employment gap are not due to systematic differences between parents and non-parents within a region.

As others have found, there is no penalty for having a first child among men as  $\hat{\alpha}_2$  is small and not statistically significant. Interestingly, there is a positive association between childless men and non-traditional gender norms of the grandmothers' cohort ( $\hat{\alpha}_1$ ), measured more precisely in our preferred specification shown in column (6). The estimated coefficient in this specification suggests that an increase in the predicted average disagreement on the priority of male employment when jobs are scarce of women in the grandmothers' cohort by one standard deviation is associated with an increase in the likelihood of employment *among childless men* of 12.5 percentage points<sup>28</sup>, the equivalent of an increase of about 18 percent in the average employment rate of childless men in our sample of 71 percent.<sup>29</sup> This effect is similar in size and significance to that of childless women, albeit the latter is less precisely estimated. Both estimates suggest that, as a result of health liberalization laws, moving gender norms towards a more egalitarian direction vis-à-vis the labor market is associated with employment gains for both males and females, regardless of parenthood decisions. This is not the first paper to find that progressive gender norms impact *both* men and women. For instance, Rodríguez-Planas and Nollenberger (2018) find that “*youth whose parents come from more gender-equal societies perform better in exams regardless of gender or subject type*”. Rodríguez-Planas, Sanz-de-Galdeano, and Terskaya (2018) also find that “*a greater proportion of peers with non-traditional mothers during high school curbs males' risky behaviors*” during high school and in their early 20s.<sup>30</sup> Either paper uses a very different identification strategy from the one in the current paper.

### ***Robustness Checks***

---

<sup>28</sup> This is calculated as:  $\hat{\alpha}_1 * \widehat{NTN}_{StDev} = 0.195 * 0.644 = 0.1256$

<sup>29</sup> This is calculated as  $\frac{\hat{\alpha}_1 * \widehat{NTN}_{StDev}}{Employment_{Mean}} = \frac{0.195 * 0.655}{0.708} = \frac{0.1256}{0.708} = 0.1773$

<sup>30</sup> An alternative and complementary potential mechanism is that non-traditional gender norms delay the marriage decision, allowing both partners to invest more in the labor market. In support of this interpretation, in Figure A-3 in the Appendix, we report significant negative correlations between our predicted gender norms and the probability of marriage of both males and females in our sample.

Using our preferred specification, Table 5 presents a battery of robustness checks for women 20- to 40-year old (column 1) and for men in the same age range (column 2). While our main finding for women holds in all of the robustness checks discussed below, it is noteworthy that, for the sample of men,  $\hat{\alpha}_3$  is zero and not statistically significant for all the robustness checks performed in Table 5. Panel A adds as additional covariates the own respondent's disagreement on the priority of male employment when jobs are scarce, and the gender norms of the respondent's cohort as additional covariates in the preferred specification. We do this to explore the extent to which the gender norms of grandmothers' cohort may be picking up the respondents' own beliefs. While own cohort's gender norms are relevant in women's decision to work, the relevance of the gender norms of the grandmothers' cohort remains large, positive and statistically significant at 7.7 percentage points. Concerns that our main findings are driven by respondents' religiosity are ruled out in Panel B, which presents results from a specification that controls for respondent's religiosity.

Panels C and D replace our left-hand-side variable (being employed or not) with two alternative outcomes: being in the labor force or not<sup>31</sup>, and hours worked, respectively. In both cases,  $\hat{\alpha}_3$  remains positive and statistically significant at the 1% level. Interestingly, the finding that the gender norms of the grandmothers' cohort is negatively associated with the motherhood employment gap holds at the intensive margin. More specifically, we find that an increase in the predicted average disagreement on the priority of male employment when jobs are scarce of women in the grandmothers' cohort by one standard deviation is associated with a reduction in the motherhood *hours worked* gap of 20 percentage points<sup>32</sup>, the equivalent of a reduction of 44 percent in the average motherhood hours worked gap in our sample.<sup>33</sup>

Next, we check the robustness of our results to alternative measurements and definitions of the gender norm variable. In Panel E, we measure non-traditional gender norms in a region as the share of grandmothers who do not have strongly conservative views regarding the position of women relative to men in the labor market. In panel F, we measure norms as the share of

---

<sup>31</sup> This is considered as being either employed or unemployed as opposed to being in education or housework as main economic status.

<sup>32</sup> This is calculated as:  $\hat{\alpha}_3 * \widehat{NTN}_{StDev} = 0.321 * 0.644 = 0.206$

<sup>33</sup> This is calculated as  $\frac{\hat{\alpha}_3 * \widehat{NTN}_{StDev}}{Motherhood\ Hours\ Worked\ Gap_{Mean}} = \frac{0.321 * 0.644}{-0.469} = \frac{0.206}{-0.469} = -0.441$

grandmothers who do not have strongly conservative views regarding the position of women in the family. In both cases, estimates are consistent with our main finding.<sup>34</sup>

Panel G to I re-estimate our preferred specification without regional controls (Panel G), parental controls (Panel H), or any individual or regional controls (Panel I). It is important to underscore that our results are robust to these alternative specifications leaving both the size and precision of our coefficient of interest  $\hat{\alpha}_3$  mostly unaffected

In Panel L, we present estimates from a two-stage least squares (2SLS) model using  $(\widehat{NTN}_{crt}^a * Small\ Child_{icrt}^{a-28})$  as an instrument for  $(NTN_{crt}^a * Small\ Child_{icrt}^{a-28})$ .<sup>35</sup> These estimates confirm that non-traditional norms of the grandmothers' cohort are directly related to maternal employment. Despite of the low F-stat, the Anderson Rubin test signals the significance of the coefficient in the second stage is robust to potentially weak instruments in the first stage (shown in Figure A-2). The coefficient of the interaction term is about ten times larger than the corresponding coefficient reported in Table 3 (column 6). We interpret this as *Local Average Treatment Effect* (LATE), in the presence of a compliance rate equal to 0.092, as measured by the first stage coefficient.<sup>36</sup> We obtain the corresponding *Intention-to-Treat* (ITT) effect as  $0.084 = 0.092 * 0.921$ . This estimated ITT effect is fully consistent with the estimate of equation (2) presented in Table 4 (Column 6), which is indeed reduced-form results of a regression of the outcome on the instrument, regardless of the compliance rate in the underlying population.

Panel M re-estimates our preferred specification adding a cohort dummy. Panel N re-estimates our preferred specification using a probit model. In both cases, results are robust to our main findings. The marginal effects reported in Panel N in Table 5 suggest very similar magnitudes to those of the linear probability model.

In Panel O, we account for country-specific time varying factors that may affect differently parents and non-parents by replacing the country-by-year fixed effects with country specific

---

<sup>34</sup> Table A-4 in the Appendix reports results from the ancillary regression.

<sup>35</sup> In practice, we use equation (2) as a 'stage 0', that predicts  $\widehat{NTN}_{crt}^a$ , and use  $(\widehat{NTN}_{crt}^a * Small\ Child_{icrt}^{a-28})$  as an instrument in the first stage of the two-stage least squares IV model. This is implemented using *ivreghdfe* in stata, which is a version of *ivreg2* which allows to absorb fixed effects (Correia 2018). This 2SLS estimator may have better asymptotic properties compared with the OLS estimator of equation (3). See Wooldridge, 2002, pp. 235.

<sup>36</sup> In this setting, the compliers are those mothers, whose norms actually respond/correlate with the treatment they are assigned to i.e. the predicted norm  $\widehat{NTN}_{crt}^a$ . Accordingly, the compliance rate is indeed the coefficient of  $\widehat{NTN}_{crt}^a * Small\ Child_{icrt}^{a-28}$  in the first stage (see Angrist and Pischke, 2009 p.164).

controls for the total number of weeks of maternity leave, and the paid weeks of maternity leave legislated in each country at time  $t$ . Doing so leaves results basically unchanged, with a negative (non-statistically significant) association between the number of paid or unpaid maternity leave weeks and female employment. In Panel P, we show a placebo test where we assign to each women a predicted norm  $\widehat{NTN}_{crt}^a$  that has been randomly drawn from a normal distribution having the same mean and the same standard deviation as our predicted norm  $\widehat{NTN}_{crt}^a$ . In this case, we find no effect of the placebo gender norm.

A final concern in our estimates is measurement error due to internal migration of grandmothers between regions, possibly in a way that is not random relative to gender norms.<sup>37</sup> To avoid possible bias, we should measure the non-traditional gender norms in the region of birth, which, however, is not available in the ESS. To address such concern, we re-estimate the fixed-effects model using gender norms measured in the region of residence at age 14. For this exercise we use a different dataset, the 2008 wave of the European Value Study (EVS), which includes the region of birth. Appendix Table A.7 replicates the analysis using both the region of residence at time of the survey (Columns 1 to 3) and when the respondent was 14 years old, (Columns 4 to 6). As our main finding remains unchanged with this alternative measure of non-traditional norms, it is unlikely that internal migration is driving our results. Importantly, estimates in Appendix Table A.7 suggest that the effect of non-traditional norms is larger and estimated more precisely when measured in the region of origin, compared to the region of residence.<sup>38</sup>

### ***Subgroup Analysis***

---

<sup>37</sup> We perform additional robustness exercises on the sample of mobile 20-40 y.o. women. In Figure A-4, we plot the average norm by current NUTS2 region of residence (on the y-axis) against the average norm in the region of origin (on the x-axis) for women with a young child (Panel A) and without children (Panel B). The two averages for each region are equally scattered around the 45 degrees line. In consecutive Panels C to F, we provide similar evidence for average female employment rates, and female-to-male Bartik wage ratios, respectively. This evidence is globally consistent with no systematic mobility pattern from more traditional regions, characterized by worse female labor outcomes, to less traditional ones, characterized by better work prospects for women.

<sup>38</sup> Notice that coefficients estimated on EVS data in Column (2) of Table A-8 are not immediately comparable to their counterparts estimated on the ESS data in column (1) of Table 3. In fact, estimates in Table A-8 are identified only by cross-regional variation in the EVS sample for 2008. Conversely, estimates in Table 3 are based on within-region variation available from the multiple waves of the European Social Survey. Accordingly, in estimates in Table A-8 we do not include region FEs, but only FEs for the 24 countries in the EVS 2008 sample (see columns 3 and 6). Standard errors are always clustered at the regional level.

Finally, Table 6 presents some heterogeneity analysis using our preferred specification. Columns (1) and (2) show that the salience of gender norms on the motherhood employment gap holds in regions with both high or low unemployment rate. Perhaps not surprisingly, the effect is stronger when the labor market is tight as there are fewer labor-demand constraints. Our main findings also hold regardless of women's educational level, as shown in columns (3) and (4). In contrast, women's parental education seems to matter as gender norms association with the motherhood employment gap is driven by those women with low socio-economic status (SES) measured by non-college educated parents. This suggests that social norms may be more stringent low-SES women, as possibly they have a higher cost of taking a career break, or a lower ability to afford child care.

### ***Female to Male Employment Gap***

Since the seminal work of Kleven et al. (2019a), the literature on the motherhood gap has shifted to comparing labor market outcomes of mothers and fathers (as opposed to those of mothers and childless women). In this section, we replicate our analysis in Table 3 using this alternative comparison group. Results are shown in Table 7. Panel A focuses on mothers and fathers, whereas Panel B does the analysis with childless women and men.

In all specifications in Panel A,  $\hat{\alpha}_3$  is positive and statistically significant at the 1% level suggesting that living in regions with more progressive gender norms among the grandmothers' cohort is associated with a higher likelihood of maternal employment relative to fathers relative to the motherhood gap in regions with more traditional gender norms among the grandmothers' cohort. Estimates in column 6 in Panel A in Table 7 show that non-traditional norms of the grandmothers' cohort are directly related to maternal employment. More specifically, we find that an increase in the predicted average disagreement on the priority of male employment when jobs are scarce in the grandmothers' cohort by one standard deviation is associated with an increase in the likelihood that mothers with small children work of 6.0 percentage points<sup>39</sup>, the equivalent of a reduction of 16.2 percent in the average motherhood employment gap in our sample of 37 percentage points.<sup>40</sup> To put it differently, if mothers from Saxony (DE3) in Germany, with an

---

<sup>39</sup> This is calculated as:  $\hat{\alpha}_3 * \widehat{NTN}_{StDev} = 0.093 * 0.644 = 0.060$

<sup>40</sup> This is calculated as  $\frac{\hat{\alpha}_3 * \widehat{NTN}_{StDev}}{Motherhood\ Gap_{Mean}} = \frac{0.093 * 0.644}{-0.371} = \frac{0.060}{-0.371} = -0.162$

average disagreement to traditional gender norms among grandmothers of 3.60 and an average employment gap of mothers relative to fathers of 22 percentage points, were characterized by the mean gender norms in Upper Norrland (SE33), which is equal to 4.168, the statistical model would suggest that the motherhood employment gap in Saxony would decrease by 5 percentage points, which would reduce by 25% the observed motherhood employment gap between Upper Norrland and Saxony (equal to 22 percentage points).<sup>41</sup>

Our preferred specification (in column 6, Panel A in Table 7) also reveals a motherhood employment gap of 64% percent (or 57.9 percentage points) of the average employment among fathers in our sample (equal to 91 percent as shown in Table A-2). While we find that the association between gender norms of the grandmothers' cohort and fathers' employment rate is positive, it is not statistically significant in this specification, albeit it is in specifications shown in columns 2 to 5. We already discussed above (page 25) that this result is not necessarily surprising given the literature findings on gender norms and males' behavioral decisions.

Panel B in Table 7 replicates the analysis for childless women and men. Interestingly, the gender gap is considerably smaller and not statistically significant, and the association between gender norms and childless women's employment is close to zero and not statistically significant. The only statistically significant coefficient (at the 10% level) is that of the gender norms of the grandmothers' cohort, suggesting a positive association between non-traditional gender norms and both childless women's and men's employment as we discussed earlier (see discussion on Table 3 above).

## 5. Addressing Endogeneity of Motherhood

A well-known fact in the motherhood gap literature is that the decision to have a child is endogenous and that *“individual unobserved heterogeneity may still prevail, as women deciding to have children may have different tastes and preferences about work than childless female workers. If there are unobserved quality differences between mothers and childless female workers, results from (repeated) cross-sectional studies of the family gap will reflect an omitted variable bias”* (Fernández-Kranz, Lacuesta, and Rodríguez-Planas 2013). To address this concern, we measure the exposure to reproductive health liberalization laws for young women (that is, 20-

---

<sup>41</sup>  $(\text{Motherhood\_Gap}(\text{DE3}) - \text{Motherhood\_Gap}(\text{SE33})) * \hat{\alpha}_3 = (4.16 - 3.60) * 0.093 = 0.56 * 0.093 = 0.05.$

to 40-year-old women) when they were 20 years old using the same dataset on reproductive health laws from Finlay, Canning, and Po (2012) and updating when need be. We then use this individual measure of exposure to reproductive health laws when respondent was 20 years old to estimate the following auxiliary regression using the sample of all 20- to 40-year-old women in the seven ESS waves covering the 2002 to 2016 period:<sup>42</sup>

$$Small\ Child_{icrt} = \rho_0 + \rho_1 Liberalization_{icr(t-age+20)} + X_{icrt}'\gamma + Z'_{crt}\delta + \varphi_r + \phi_{ct} + \varepsilon_{icrt} \quad (4)$$

In the auxiliary first stage equation (4), we exploit variation in exposure to liberalization laws across individuals within a country and for a given survey wave. Notice the difference with equation (2), where the variation in exposure was across cohorts (of grandmothers) within a certain region, within a country and a given survey wave.

The coefficient  $\hat{\rho}_1$  in equation (4) is identified if women in country  $c$  have been exposed to different degrees of liberalization based on their age. The variation we exploit to estimate equation (4) can be better understood by looking at the variation of the baseline  $Liberalization_{ct}$  indicator by Finlay Canning and Po (shown in Figure A-1 in the Appendix). This is different from the variable  $GrandExposure20^a_{crt}$  in eq. (2), which measured the average degree of liberalization to which the cohort  $a$  of grandmothers in country  $c$ , region  $r$ , and time  $t$ , was exposed at the age of 20y.o. As we argue below, the two indicators exploit different sources of variation.

Panel B in Table 3 shows results from three different probit estimates of auxiliary regression (4). In column 1,  $Liberalization_{icr(t-age+20)}$  uses both abortion and pill liberalization laws; in column 2,  $Liberalization_{icr(t-age+20)}$  is entered separately in the equation based on either pill or abortion liberalization laws; and in column 3,  $Liberalization_{icr(t-age+20)}$  only uses abortion liberalization laws. Estimates in Panel B, Table 3 show that greater exposure to reproductive health laws when respondents were in their 20s is associated with lower likelihood of being a mother up to two decades later with coefficients always statistically significant at the

---

<sup>42</sup> As this auxiliary regression does not include the non-traditional norms variable, we are able to use all seven waves, increasing sample size and maximizing exogenous variation to identify the effect of the degree of reproductive health liberalization laws on the decision to have a child.

1% level. The results suggest that the  $Liberalization_{icr(t-age+20)}$  indicator is important to explain maternity decisions.

From the first stage in equation (4) above, we estimate the predicted probability of having a child,  $\widehat{SmallChild}_{icrt}^{a-28}$  for all 20- to 40-year-old females in our sample, and use such predicted estimator in the equation (5) below:

$$Y_{icrt}^{a-28} = a_0 + a_1 \widehat{NTN}_{crt}^a + a_2 \widehat{SmallChild}_{icrt}^{a-28} + a_3 (\widehat{NTN}_{crt}^a * \widehat{SmallChild}_{icrt}^{a-28}) + X_{icrt}^{a-28'} \gamma + Z'_{crt} \delta + \lambda_a + \varphi_r + \phi_{ct} + \varepsilon_{icrt}^{a-28} \quad (5)$$

Our estimate of interest,  $\widehat{a}_3$ , captures the association between predicted non-traditional norms of the grandmothers' cohorts and predicted motherhood probability relative to childless women (conditional on the included covariates). We argue that the actual realization of motherhood depends on the direct exposure of our female respondents to reproductive-health liberalization laws implemented in their country when they were 20 years old. Our assumption is that the country's degree of reproductive-health liberalization when the respondent was 20 years old is correlated with women's decision to become mothers, however, contrary to the actual decision to have a child, the country's degree of reproductive-health liberalization when respondent was 20 (i) is not (contemporaneously) affected by labor market outcomes and (ii) is likely to affect women's decision to work only through motherhood.

While  $\widehat{a}_3$  estimated from equation (3) measured the effect of the predicted non-traditional gender norm by motherhood status,  $\widehat{a}_3$  estimated from equation (5) measures the effect of the predicted non-traditional gender norm by predicted exposure to motherhood based on liberalization laws when the respondent was 20 years old. Notice that equation (5) is exactly identified as there are two instruments for two endogenous regressors. Notice that identification of  $\widehat{NTN}_{crt}^a$  and  $\widehat{SmallChild}_{icrt}^{a-28}$  in equation (5) comes from exposure to different reproductive health liberalization laws from equations (2) and (4). In fact,  $\widehat{NTN}_{crt}^a$  is identified by changes in the degree of liberalization taking place between 1956 and 1988, while  $\widehat{SmallChild}_{icrt}^{a-28}$  is identified by changes in liberalization occurring between 1982 and 2016. This implies that while any change in liberalization taking place in country  $c$  between 1982 and 1988 contributes to the identification of both indicators. reforms during 1956-1982 and 1988-2016 guarantee that the

effects of  $\widehat{NTN}_{crt}^a$  and  $\widehat{SmallChild}_{icrt}^{a-28}$  are both identified in equation (5). The indicators of exposure are positively correlated (with a correlation coefficient of 0.46, significant at the 1% level). Yet, the two predicted variables  $\widehat{NTN}_{crt}^a$  and  $\widehat{SmallChild}_{icrt}^{a-28}$  display no correlation (correlation of 0.007, not statistically significant).

Table 8 re-estimates Table 4 but replacing observed maternity status with the predicted exposure to maternity,  $\widehat{SmallChild}_{icrt}^{a-28}$ , estimated from the auxiliary regression (4). In Column 1, we report results using the observed  $NTN_{crt}^a$ . In Columns 2 and 3, we present results from estimating model (5) in which, in addition to addressing endogenous motherhood, the potentially endogenous non-traditional gender norms variable has been replaced with its predicted measure,  $\widehat{NTN}_{crt}^a$ , estimated from the auxiliary equation (2). The difference in the specification between columns 2 and 3 is that the former exploits variation in exposure to both the pill and the abortion liberalization laws, whereas the latter only exploits variation in exposure to abortion liberalization laws. Column 4 in Panel A in Table 8 re-estimates the model used in column 2 but only including in the sample respondents who were born after such legalizations took place, and column 5 re-estimates the specification in Column 4 excluding respondents from countries in which grandmothers were not affected by any changes in the reproductive health laws when they were in their 20s.

In five out of six specifications,  $\widehat{a}_3$  is positive and statistically significant at the 5 percent level or lower consistent with earlier findings that living in regions with more progressive gender norms among the grandmothers' cohort is associated with a smaller motherhood employment gap. Crucially, when all six specifications are estimated using fathers and childless men (shown in Panel B in Table 8), the size of  $\widehat{a}_3$  is considerably smaller and the coefficient is not statistically significant.

Based on our preferred specification, shown in column 6, Panel A in Table 8, a one-standard deviation increase in the predicted average disagreement on the priority of male employment when jobs are scarce of women in the grandmothers' cohort is associated with an increase in the maternal employment of 9.17 percentage points—note that the predicted probability of becoming mothers averages 0.28 as shown in Table A-4 in the Appendix.<sup>43</sup> This is equivalent

---

<sup>43</sup> This is calculated as:  $a_3 * NonTraditionalBeliefs_{StdDev} * \widehat{SmallChild}_{StdDev} = 0.515 * 0.646 * 0.28 = 0.0917$

to a reduction of about 80 percent in the average motherhood employment gap in our sample of 12 percentage points.<sup>44</sup>

After addressing the endogeneity of motherhood, the effect of grandmothers' cohort non-traditional norms increases by 70 percent—as a one-standard-deviation increase in non-traditional norms reduced the motherhood employment by 47 percent prior to correcting for the endogeneity of motherhood (column 6, Panel A in Table 4), and by 80 percent after correcting for motherhood endogeneity (column 6, Panel A in Table 8). Once we correct for the endogeneity of motherhood, the association between grandmother's cohort gender norms and childless women employment (captured by  $\widehat{a}_1$ ) is considerably smaller and no longer statistically significant. This suggest that non-traditional gender norms mediate on female employment mainly via motherhood, which brings a novel insight in this literature on culture and female employment.

While the results that deal with endogeneity of motherhood have internal validity as they address the endogeneity of motherhood, it is unclear whether they would generalize to the whole population as identification mostly comes from reproductive health variation moving to less restrictive laws. Indeed, only one country (Poland) in our sample enacted more restrictive reproductive health laws in the time period we are analyzing.

## 6. Conclusion

Using individual-level data from the European Social Survey, this paper studied the relevance of gender norms in accounting for the motherhood employment gap across 186 European NUTS2 regions (over 29 countries) for the 2002-2016 period. Following the insight coming from the literature, we measured gender norms based upon beliefs on the preferential role of men vs. women in the labor market, or on the preference that women should give to the family vs. the labor market. We address the potential endogeneity of our gender norms measure with an index of the degree of reproductive health liberalization when grandmothers were 20 years old. We also account for the endogeneity of motherhood with the level of reproductive health liberalization when mothers were 20 years old, and we show robustness of the results to alternative definitions of gender norms. We find a robust positive association between progressive beliefs among the grandmothers' cohort and mothers' likelihood to work while having a small child (0 to 5 years

---

<sup>44</sup> This is calculated as  $\frac{a_3 * \widehat{NTN}_{StDev} * \widehat{SmallChild}_{StDev}}{Motherhood\ Gap_{Mean}} = \frac{0.515 * 0.644 * 0.281}{-0.116} = \frac{0.0917}{-0.116} = -0.803$

old) relative to similar women without children. No similar association is found among men. At the same time, we also find a robust positive association between progressive beliefs among the grandmothers' cohort and mothers' likelihood to work while having a small child (0 to 5 years old) relative to similar fathers. No similar association is found among childless women and men.

Our analysis underscores the role of gender norms and maternal employment, suggesting that non-traditional gender norms mediate on the employment gender gap mainly via motherhood. We believe this is an important message that underscores the importance of gender equal policies such as an equal parental leave, compulsory for both parents. Our results suggest that such policies, besides helping young mothers to come back on the labor market more quickly, may also have deeper and long-lasting effects on the labor supply of mothers, by fostering the creation of a more gender egalitarian culture in the long run.

Figure 1: NTN Sample Average 2004-2016 by Cohort

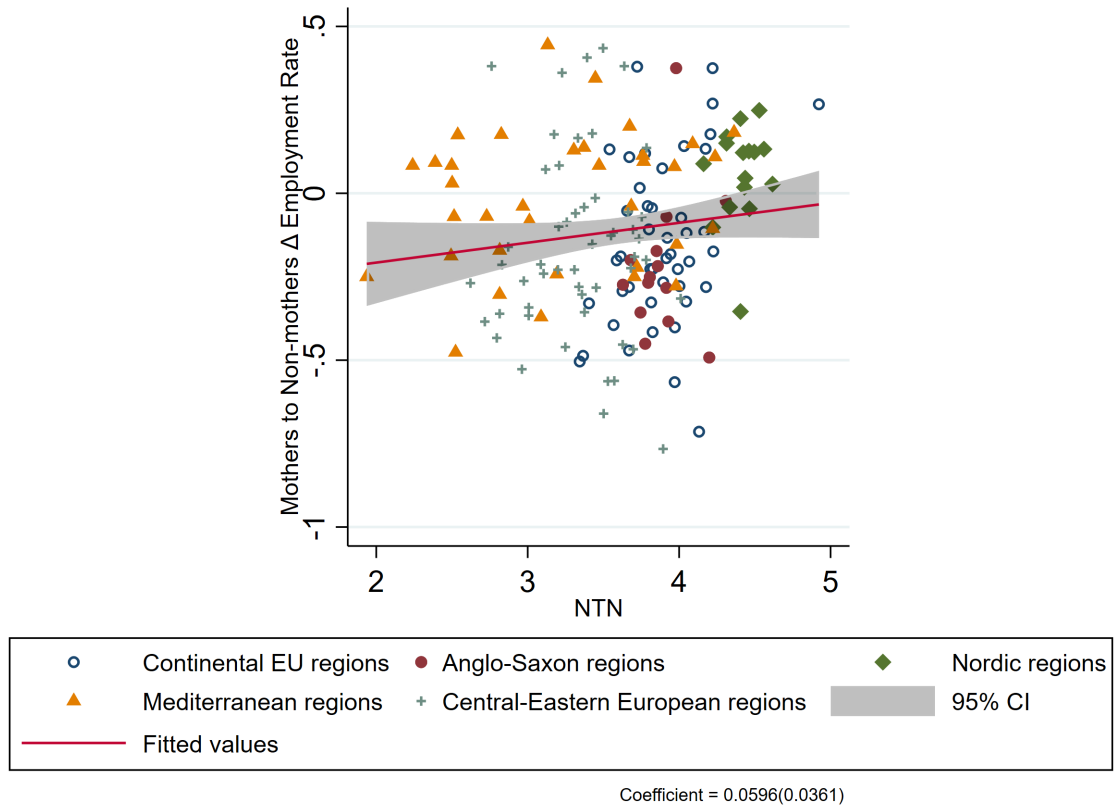

**Notes:** Non-traditional norm (NTN) represented in the Y axis refers to the average extent of disagreement (1-5 scale) to the statement ‘when jobs are scarce, men should have more right to a job than women’ within the ESS region at the NUTS-2 level. Non traditional norm is measured as the average extent of disagreement (1-5 scale) to the statement ‘when jobs are scarce, men should have more right to a job than women’ within the ESS region. The lines plot average norms over ESS round 2004, 2008, 2010 and 2016 for the two cohorts of grandmothers aged 48-57 y.o., and grandmothers aged 58-68 y.o.

Figure 2: NTN, Cross-Regional Variation by Cohort

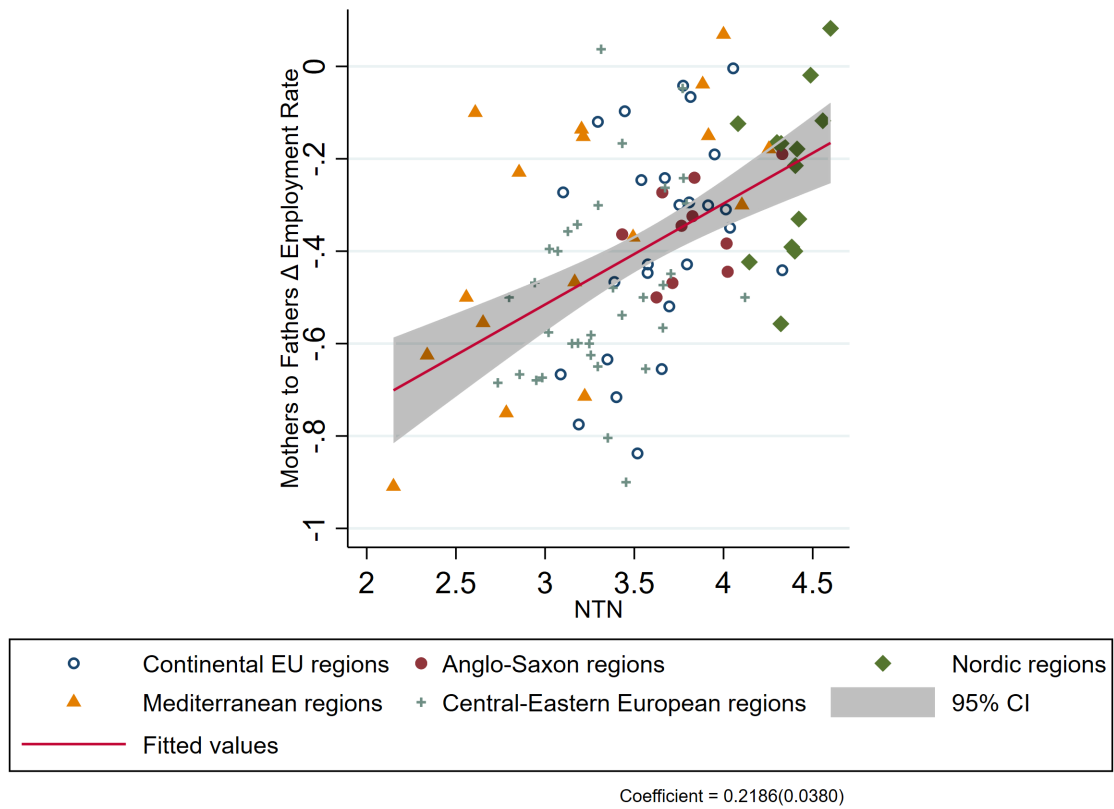

**Notes:** Non-traditional norm (NTN) represented in the Y axis refers to the average extent of disagreement (1-5 scale) to the statement *‘when jobs are scarce, men should have more right to a job than women’* within the NUTS2 region, in a given year (i.e. 2004,2008,2010,2016). On the Y axis the average norm measured across grandmothers aged 58-68 Y.O. On the X-axis the average norm across grandmothers aged 48-57 Y.O. The graph plots the total variation (regional and overtime) within the sample.

Figure 3: First Child Employment Penalties and Elicited Gender Norms

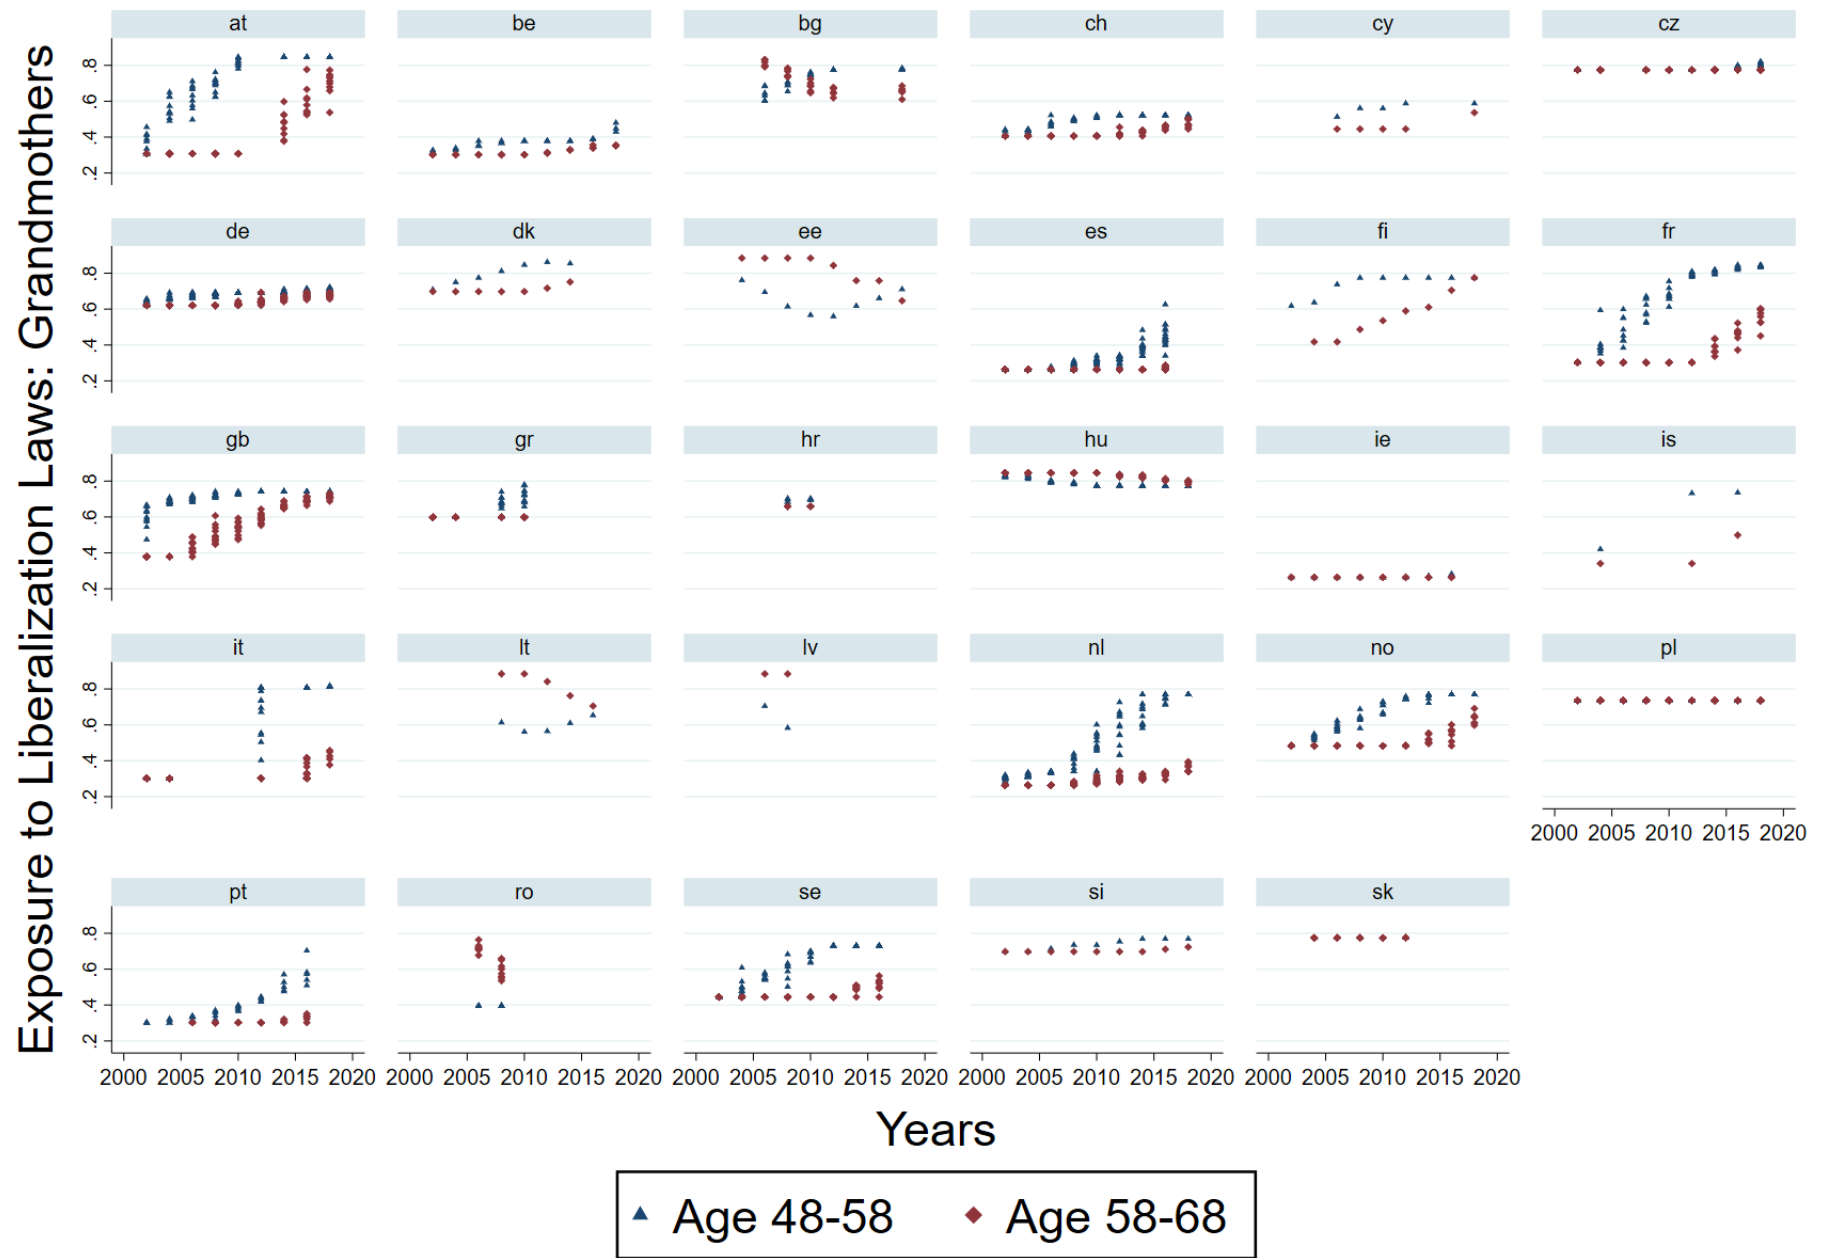

(a) Non-mothers to mothers

(b) Fathers to mothers

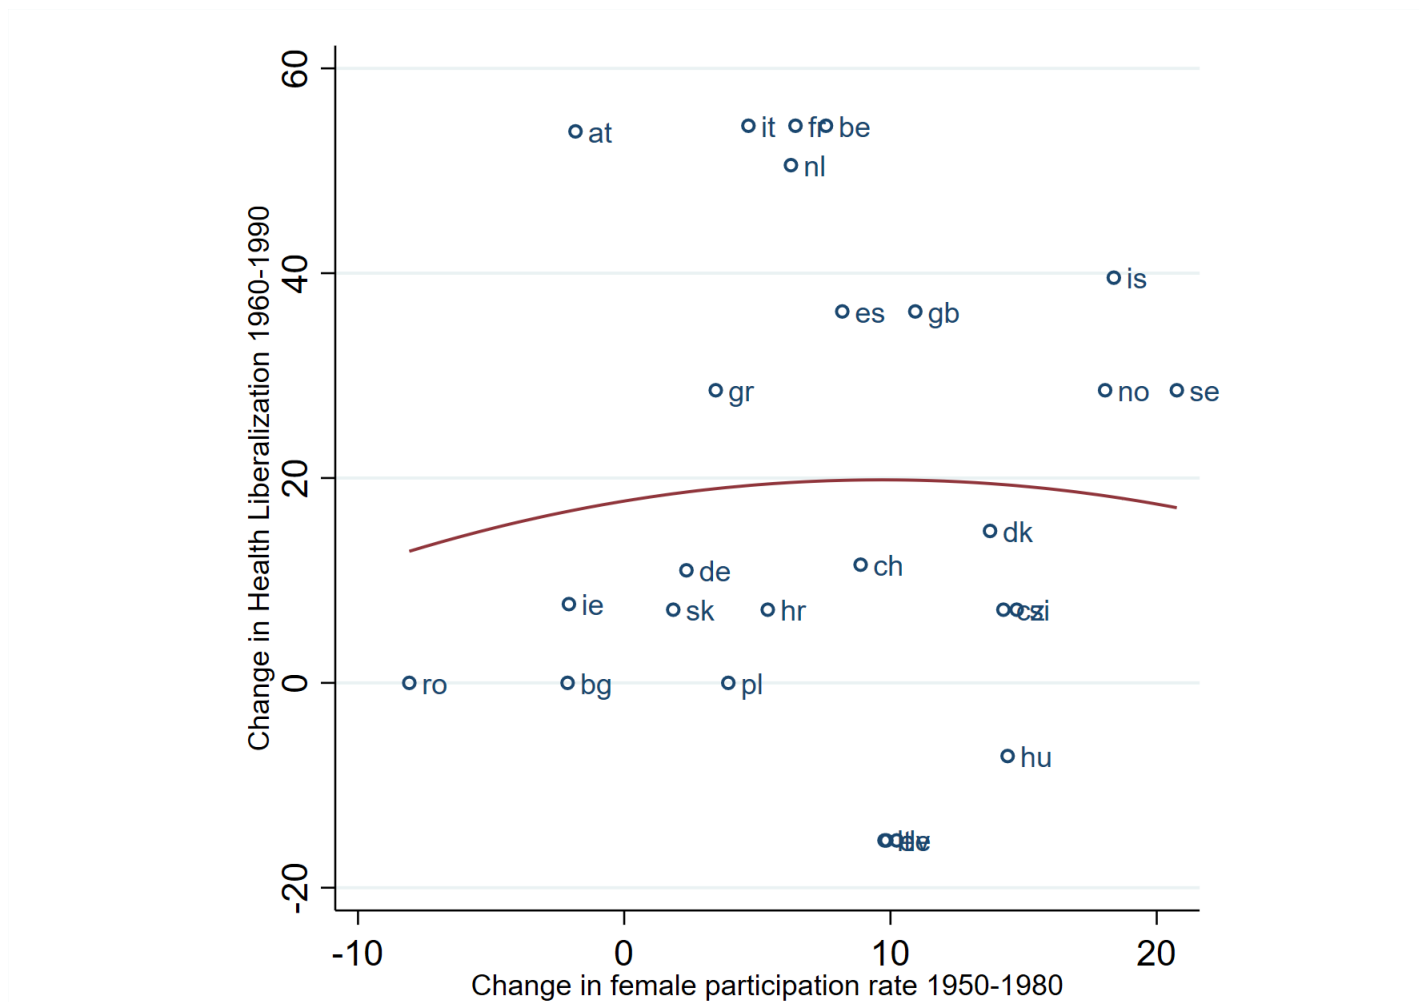

**Notes:** Non-traditional norm (NTN) represented in the X axis is measured as the average extent of disagreement (1-5 scale) to the statement ‘when jobs are scarce, men should have more right to a job than women’ within the ESS region at the NUTS-2 level. The Y axis in figure 3a shows differences in average employment rates between mothers (first child 0-5 Y.O.) and non-mothers within each region. The Y axis in figure 3b shows the differences in average employment rates between mothers (first child 0-5 Y.O.) and fathers.

Figure 4: Grandmothers' Exposure to Contraceptive Pill and Abortion Liberalization

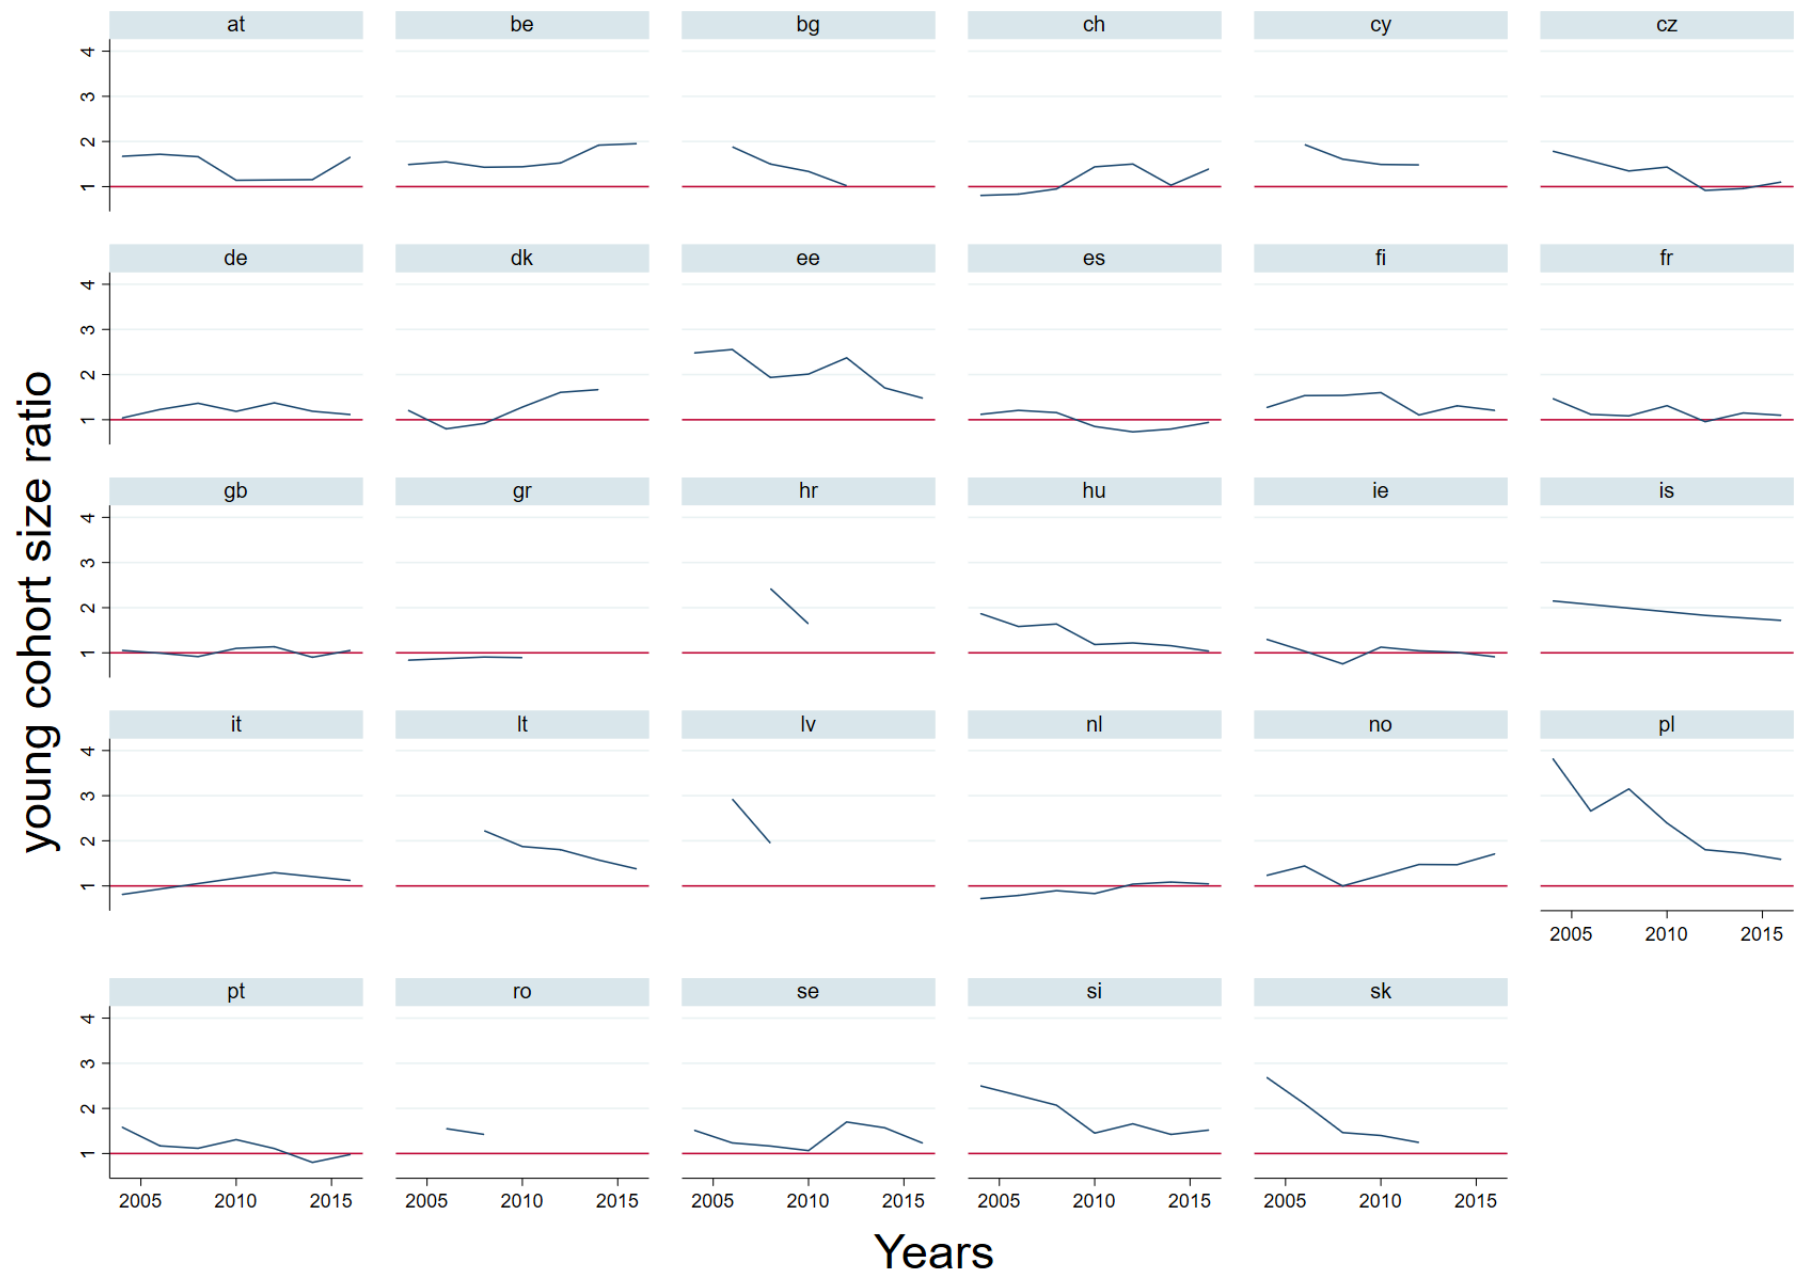

**Notes:** On the X axis the year of the ESS round 2002-2018. On The Y axis the degree of average degree of reproductive health laws liberalization (contraceptive pill and abortion) to which the cohort of grandmothers in the region was exposed to at the age of 20 y.o. (max=1). Each dot indicates the average exposure of grandmothers in the corresponding cohort in the region. Authors' calculation on data from ESS and Finlay, Canning, and Po (2012).

Figure 5: Reproductive health liberalizations 1960-1990 vs. past changes of gender norms

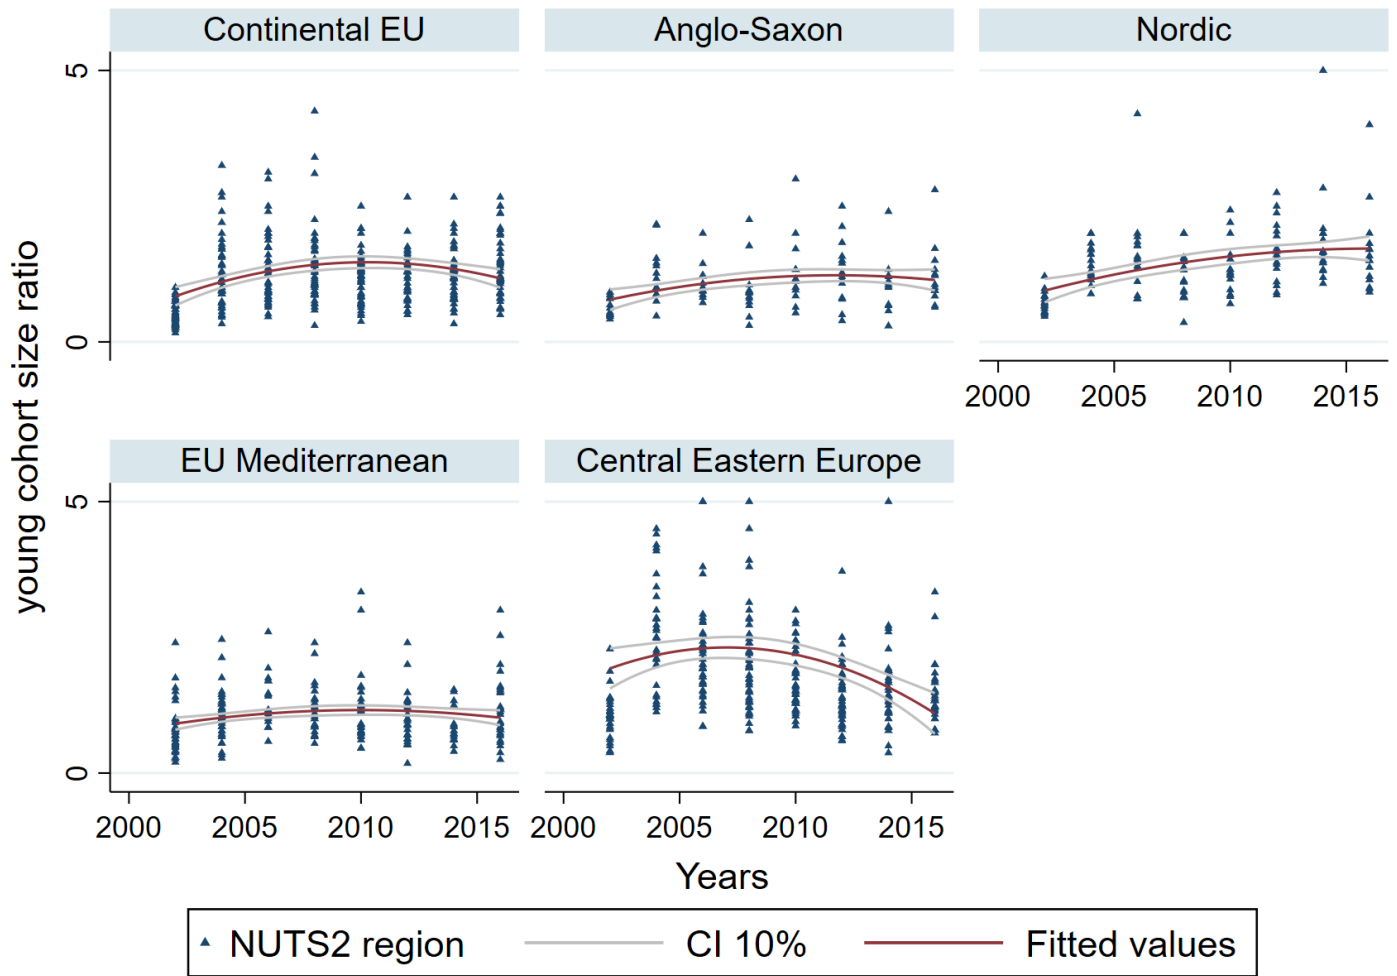

**Notes:** On the X axis find the change in female participation rate between 1950 and 1980, following the definition by Fernandez and Fogli (2009). Data are taken by Gay (2023), and have been completed using data from Table 4 of ILO (1997). The Y axis reports the change of the degree of liberalization of health laws between 1960 and 1990. Authors' calculation on data from Gay (2023), International Labour Office, Bureau of Statistics (1997), and Finlay, Canning, and Po (2012).

Figure 6: Ratio between the two cohorts of grandmother - Country-Level Variation

Notes: On The Y axis the ratio between the size of the young cohort of grandmothers (aged 48-57 y.o.), relative to the old cohort (aged 58-68) during our sample period. Authors' calculation on data from the European Social Survey.

Figure 7: Ratio between the two cohorts of grandmother - Regional-Level Variation

Notes: On The Y axis the ratio between the size of the young cohort of grandmothers (aged 48-57 y.o.), relative to the old cohort (aged 58-68) during our sample period. Authors' calculation on data from the European Social Survey.

Table 1: Balancing Test

	Mothers	Non-Mothers	Fathers	Non-Fathers

Share with tertiary ed.	0.232 (0.148)	0.047 (0.126)	-0.143 (0.155)	0.056 (0.121)
Unemployment rate	0.121 (0.143)	0.176 (0.145)	0.099 (0.174)	0.134 (0.140)

**Notes:** The table shows the relationship between the non-traditional norm (NTN) which is the dependent variable and the particular individual, parental or regional control over different samples. Column [1] reports the correlation in the sample of mothers (with first child 0-5 Y.O.); column [2] reports the correlation for the sample of non-mothers; columns [3] and [4] consider the samples of fathers (first child 0-5 Y.O.) and non-fathers, respectively. All specifications include a dummy for the age group 20 to 30 year old, as well as country-by-year and regional dummies. Robust standard errors, clustered at the regional level in parentheses. Significance levels: \*: 10% \*\*: 5% \*\*\*: 1%

Table 2: Pre-trend analysis: Change in the degree of health liberalization and variation of norms 1960-1990

dependent variable	$\Delta_t$ (liberalization)	$\Delta_t$ (liberalization)
$\Delta_{t-10}$ (female participation rate)	−0.049 (0.316)	−0.522 (0.329)
year fixed effects	no	yes
Observations	136	136

**Notes:** The dependent variable is the change in the country-level degree of liberalization between time  $t - 10$  and time  $t$ . The regressor is the ten years lagged variation of the female participation rate. Panel regressions for 29 countries over the 1960-1990 period (ten years' variation). Data are taken from Gay (2023), International Labour Office, Bureau of Statistics (1997), and Finlay, Canning, and Po (2012). Robust standard errors in parentheses. Significance levels: \*: 10% \*\*: 5% \*\*\*: 1%

Table 3: Auxiliary NTN and Motherhood Regressions

	(A) NTN (Grandmothers 48/68 Y.O. in the Region)			(B) Women 20/40 Y.O.		
	(1)	(2)	(3)	(4)	(5)	(6)
	NTN	NTN	NTN	Child 0-5	Child 0-5	Child 0-5
Exposure to Abortion or Pill Liberalizations	0.691*** (0.121)			-1.434*** (0.252)		
Exposure to Abortion Liberalizations		0.378*** (0.068)	0.329*** (0.076)		-0.463*** (0.091)	-0.534*** (0.086)
Exposure to Pill Liberalizations			0.434 (0.303)		-2.210*** (0.435)	
Observations	1250	1255	1250	29879	28981	28981
Adj. R-squared	0.635	0.634	0.635			
Pseudo R-Squared				0.078	0.084	0.074
(Adj./Pseudo) R-squared with no exposure	0.625			0.069		

**Notes:** Regressions in Columns (1)-(3) are at the regional level and include regional characteristics (total population, fertility rate, unemployment rate and share of tertiary educated). Regressions in columns (4)-(6) include the usual set of individual characteristics (i.e. tertiary and secondary education dummies, age, age-squared, two dummies for marital status, a dummy for being in a low income household, dummy for own unemployment experience), parental characteristics (two dummies father, mother working when the respondent was 14) and regional characteristics (total population, fertility rate, unemployment rate and share of tertiary educated). All specifications also include region and country by year fixed effects. Results from regression in column (1) are used to predict  $\widehat{NTN}$  used in Tables 4, and 8, columns [2],[4],[5]. Results from regression in column (1) are used to predict  $\widehat{NTN}$  used in Table 4, column [3]. Results from regression in column (3) are used to predict  $\widehat{NTN}$  used in Tables 4 and 8, column [3]. Results from regression in column (4) are used to predict  $\widehat{Child}$ , which is used as a regressor in Table 8. Standard errors are clustered at the regional level in parentheses. Significance levels: \*: 10% \*\*: 5% \*\*\*: 1%

Table 4: Non-Traditional Norm (NTN) and Employment - Motherhood Gap Estimator

Observations	15998	15998	15998	9280	7735	8767
$\widehat{NTN}$ predicted from Pill & Abortion	No	Yes	Yes	Yes	Yes	Yes
$\widehat{NTN}$ predicted from Abortion only	No	No	No	No	No	No
Respondent born after abortion legalization	No	No	No	Yes	Yes	Yes
Respondent born after pill legalization	No	No	No	No	Yes	No
no reform countries dropped	No	No	No	No	No	Yes

**Notes:** The sample includes male and females aged 20-40 years old. The dependent variable is a dummy = 1 if individual is employed and 0 otherwise. Child stands for *Small Child* in equation (3). In Column [1], NTN refers to the average NTN for each ESS round (2004, 2008, 2010 and 2016), each cohort of grandmothers (48-57 y.o., and 58-68 y.o.) in the region. In Column [2], we use  $\widehat{NTN}$  predicted from Column [1] of Table 3. In Column [3], we use  $\widehat{NTN}$  from Column [3] of Table 3. For estimates in Column [4], we drop respondents born before the legalization of abortion, and in Column [5] we also drop respondents born before the legalization of the pill. For estimates in Column [6], we drop countries that do not exhibit variation in the exposure indicator. All specifications include individual characteristics (i.e. tertiary and secondary education dummies, age, age-squared, two dummies for marital status, a dummy for being in a low income household, dummy for own unemployment experience), parental characteristics (two dummies father, mother working when the respondent was 14) and regional characteristics (total population, fertility rate, unemployment rate and share of tertiary educated), regional and country by year FE. Bootstrapped standard errors (200 rep.) clustered at the regional level in parentheses. Significance levels: \*: 10% \*\*: 5% \*\*\*: 1%

Maternity: Paid Weeks	-0.001* (0.001)	-0.000 (0.001)		

**Notes:** Baseline specification is the one of Table 4, column (6). In Panels E, F  $\widehat{NTN}$  is predicted from regressions described in Table A-4 columns (1), and (4), respectively. All specifications include regional and country by year FE, but specifications in Panel I where country-by-year FE are replaced by country-specific controls for maternity leave legislation. In Panel P,  $\widehat{NTN}^p$  is a randomly constructed norm drawn from a normal distribution having the same mean and the same standard deviation as  $\widehat{NTN}$ . Bootstrapped standard errors (200 replications), clustered at the regional level in parentheses in all specifications but in Panel L, where they are only clustered at regional level (no bootstrapping). Significance levels: \*: 10% \*\*: 5% \*\*\*: 1%

Table 6: Heterogeneity: Economic Conditions and Education Background of the Respondent

	[I] Unemployment Rate		[II] Own Education		[III] Parental Education	
	(1)	(2)	(3)	(4)	(5)	(6)
	Below Median	Above Median	Below Median	Above Median	Below Median	Above Median
$\widehat{NTN} \times \text{Child}$	0.174*** (0.039)	0.060** (0.028)	0.084*** (0.030)	0.080** (0.040)	0.114*** (0.026)	-0.015 (0.044)
Observations	3834	4334	4727	3441	5431	2737

**Notes:** The sample includes female respondents aged 20-40 years old. All specifications include the usual extensive set of individual characteristics, parental characteristics, and regional characteristics. The unemployment rate is omitted from regional controls in Panel [I]. Own education is omitted from specification in Panel [II]. A parental background characterized by tertiary education is defined as at least one of the parents of the respondent having completed tertiary education. All specifications also include regional and country by year FE. Bootstrapped standard errors (200 replications) clustered at the regional level in parentheses. Significance levels: \*: 10% \*\*: 5% \*\*\*: 1%

Table 7: Non-Traditional Norm (NTN) and Employment - Female-to-Male differences

**Notes:** The table replicates exactly Table 4, but replaces to the dummy *Child*, the probability  $\widehat{Child}$  of having a child predicted from Column [4] of Table 3. All specifications include the usual set of extensive set of individual characteristics, parental characteristics, and regional characteristics, regional and country by year FE. Bootstrapped standard errors (200 rep.), clustered at the regional level in parentheses. Significance levels: \*: 10% \*\*: 5% \*\*\*: 1%

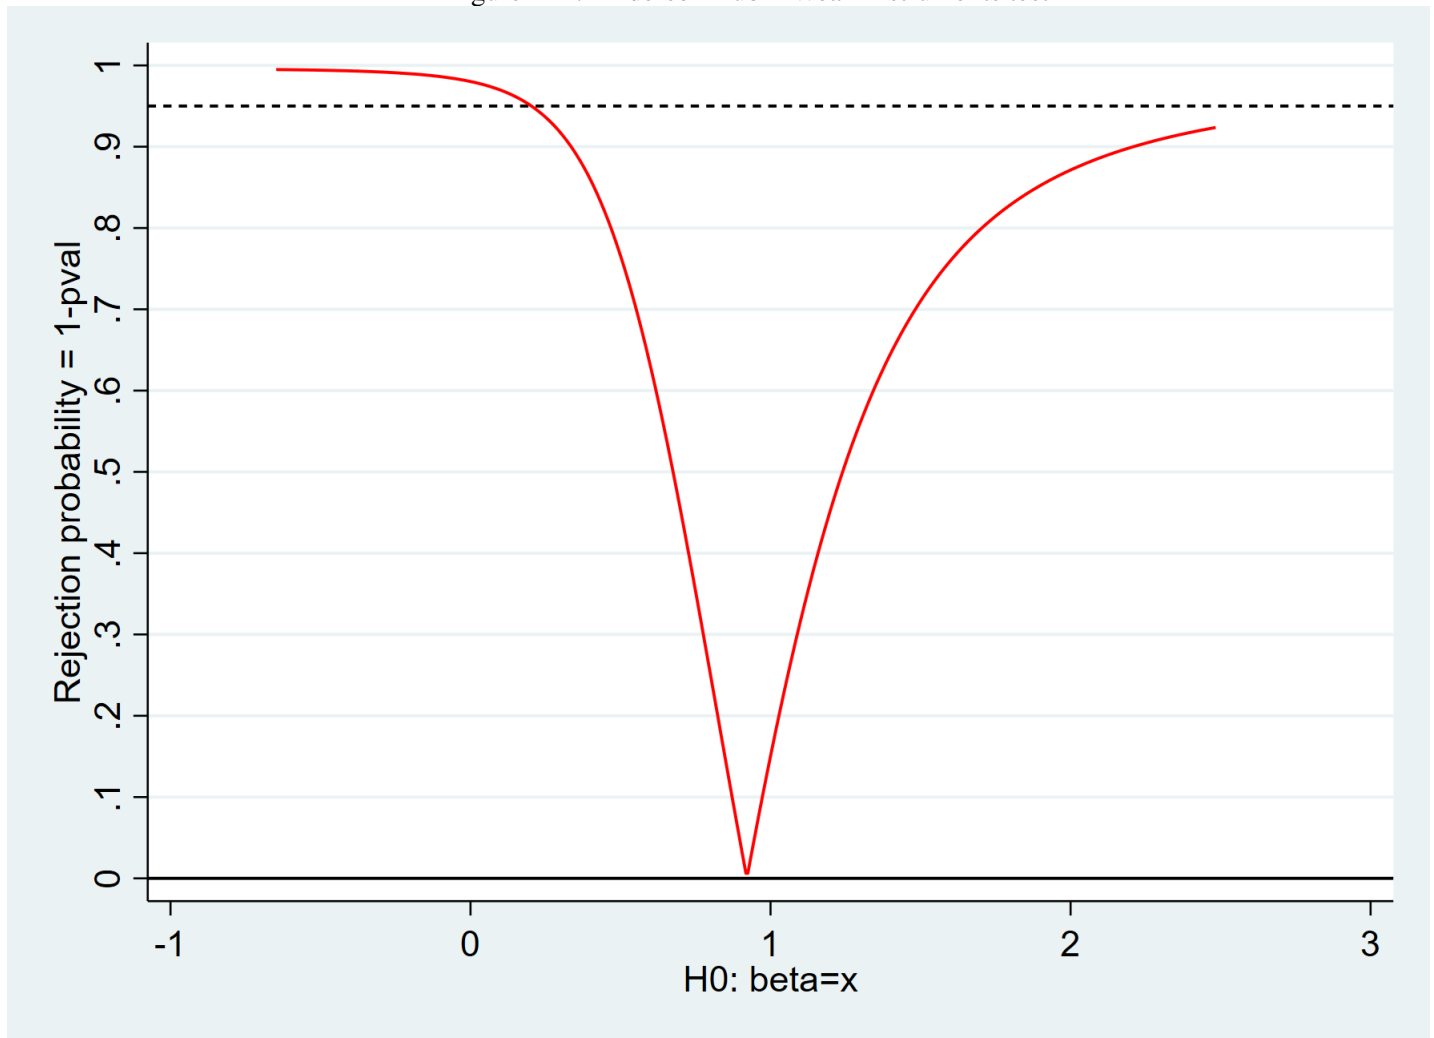

## A Appendix

Figure A-1: Exposure to Liberalization Index - Sample Variation

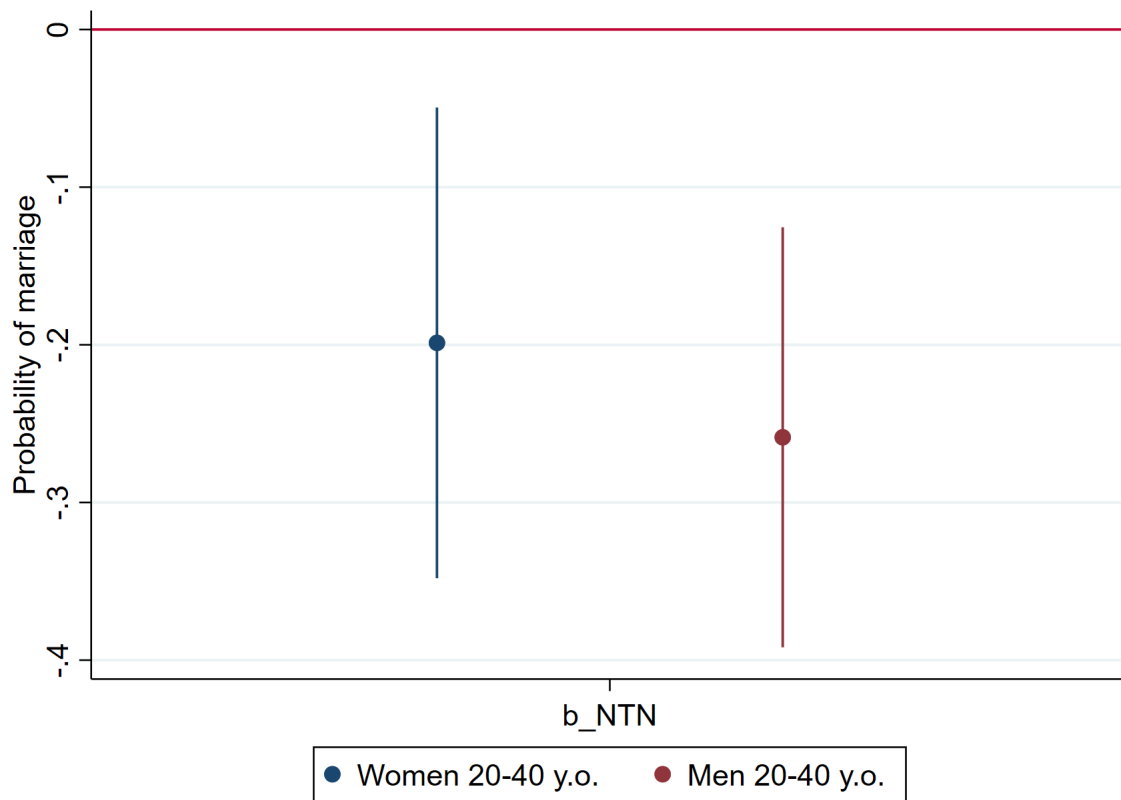

Notes: On The Y axis the degree of average degree of liberalization to in the country between 1960 and 2018. Authors' calculation on data from Finlay, Canning, and Po (2012).

Figure A-2: Anderson Rubin Weak Instruments test

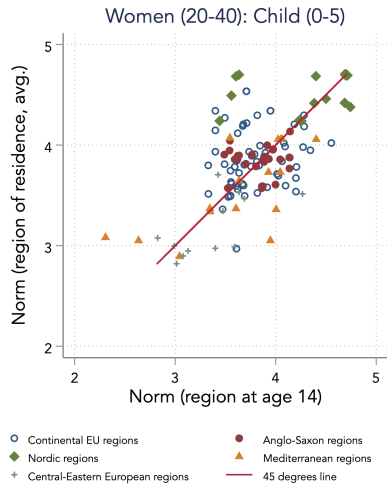

**Notes:** Probability of rejection of the Null hypothesis  $\beta_0 = \beta$ , based upon the Chi2 Statistic (5.43), computed based upon the lagrange multiplier method. 90% confidence interval is [.339543, 2.20705]. AR Test refers to 2SLS estimates reported in Panel L of Table 5.

Figure A-3: Non Traditional Norm and Probability of Marriage

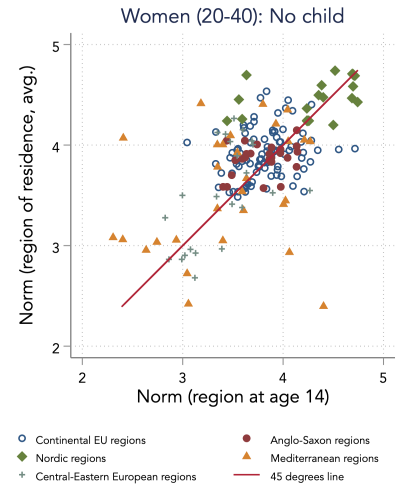

Notes: on the y-axis the coefficient of  $\widehat{NTN}$  in a linear probability model where the dependent variable is a dummy equal to one if the respondent is married, 0 otherwise. The regression is conditional on age, age squared, two dummies for mother working, and father working at respondent's age of 14 y.o. Regressions are run separately for males and females. The blue dot is the estimated coefficient of  $\widehat{NTN}$  for regression on females, while The red dot is the estimated coefficient of  $\widehat{NTN}$  for regression on males. Confidence intervals are computed based on bootstrapped standard errors, clustered at the regional level.

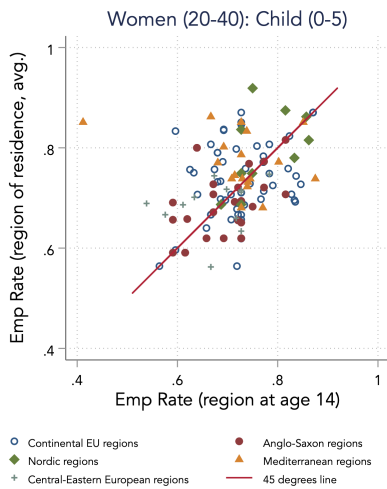

Figure A-4: Region of Residence versus Region of Birth

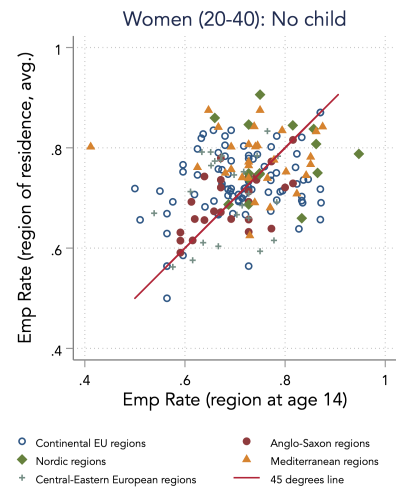

(a) EVS Migration (NTN)

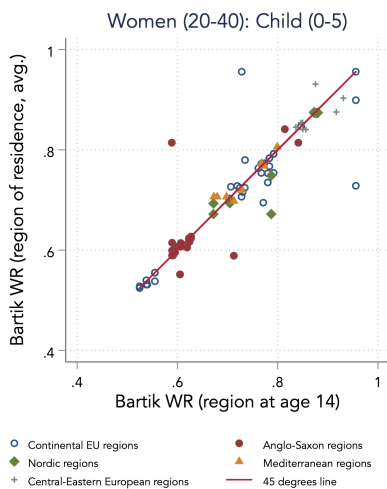

(b) EVS Migration (NTN)

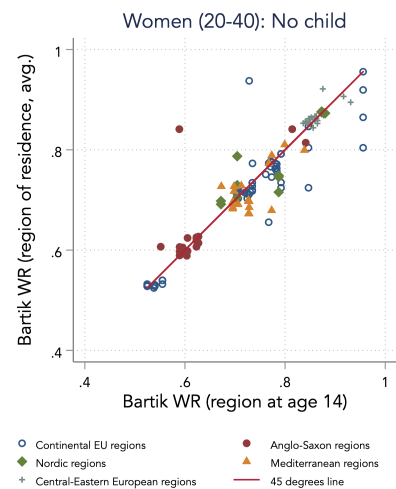

(c) EVS Migration (Employment)

(d) EVS Migration (Employment)

(e) EVS Migration (Bartik Wage Ratio)

(f) EVS Migration (Bartik Wage Ratio)

Notes: figures plotted using the EVS data for 20-40 Y.O. women. Figure A-4a and A-4d consider the average norm at the region of residence and the norm at the region when the respondent was 14 Y.O. for every combination of region of residence and region at age 14. Figure A-4a refers to mothers (first child 0-5 Y.O.) and A-4d considers childless women. The norm in the EVS dataset refers to the response to the following question "Men should have more right to a job than women (agree or disagree)?" Figure A-4c and A-4d compares average employment rates at the region of residence and the employment rates at the region when the respondent was 14 Y.O. for each combination of region of residence and region at age 14. Figure A-4e and A-4f show the relationship between average bartik wage ratio at the region of residence and the bartik wage ratio at the region when the respondent was 14 Y.O. for every each combination of region of residence and the region at age 14.

Table A-4: Auxiliary NTN regression (alternative NTN measurement &amp; definition)

	NTN: gender roles in the labor market			NTN: gender roles in the family		
	(1)	(2)	(3)	(4)	(5)	(6)
Exposure to Abortion or Pill Liberalizations	0.069*** (0.023)			0.110*** (0.036)		
Exposure to Abortion Liberalizations		0.041*** (0.014)	0.041*** (0.014)		0.062*** (0.020)	0.058*** (0.022)
Exposure to Pill Liberalizations			-0.002 (0.025)			0.039 (0.080)
Observations	1250	1255	1250	961	966	961
Adj. R-squared	0.55	0.55	0.55	0.57	0.57	0.57
Adj. R-squared with no exposure	0.55			0.57		

**Notes:** All regressions are carried out at the regional level and include regional characteristics (total population, fertility rate, unemployment rate and share of tertiary educated). In columns (1)-(3), NTN is the share of grandmothers in each cohort who does not strongly agree with the statement '*when jobs are scarce, men should have more right to a job than women*'. In columns (4)-(6), NTN is the share of grandmothers in each cohort who does not strongly agree with the statement '*women should cut on work for the sake of family*'. This definition stresses women's nurturing role as well as gender distribution of childrearing. All specifications also include region and country by year fixed effects. Results from regression in columns (1) and (4) are used to predict  $\widehat{NTN}$  used in Tables 5, Panel F. Standard errors are clustered at the regional level in parentheses. Significance levels: \*: 10% \*\*: 5% \*\*\*: 1%

Table A-5: Descriptive Statistics of Observed and Predicted Norm and Motherhood Values
